## OBJECTIVES

- To review the main characteristics of the inflammatory process and its association with cancer.
- To understand how vitamin D prevents the development and progress of chronic inflammation.
- To understand the role of vitamin D in the anti-inflammatory actions of the immune system.
- To review the role of vitamin D in the most common inflammatory diseases.
- To understand which major molecular pathways of inflammation-associated cancers are modulated by vitamin D.
- To present concrete examples of how vitamin D affects the major inflammatory and cancer-promoting pathways in the intestines, prostate, breast, pancreas, and liver.

## 1. Introduction

Cancer arises due to accumulation of genetic changes that lead to acquisition of so-called hallmarks of cancer: self-sufficient proliferation, insensitivity to anti-proliferative stimuli, resistance to apoptosis, unlimited replicative and angiogenic potential, and the ability for invasion and metastasis [1]. Genomic instability and inflammation foster the acquisition of these hallmarks. The link between cancer and inflammation is based on

the observations that tumors often develop at sites of chronic inflammation and that inflammatory cells are found in the tumor tissue. In addition, the immune system affects cancer development through both pro- and anti-tumorigenic mechanisms, as recently reviewed by Greten and Grivnickov [2].

The inflammatory process is the response of the host to microbial infection or to tissue injury and is responsible for maintaining tissue homeostasis. Controlled inflammation protects against infection and tissue damage. Uncontrolled inflammation leads to autoimmunity and the development of multifactorial diseases, such as type 2 diabetes, inflammatory bowel disease (IBD), neurodegenerative diseases, asthma, chronic rheumatic disorders, and cancer [3]. Numerous chronic inflammatory diseases, such as pancreatitis, colitis, and hepatitis, are recognized risk factors for cancer of the pancreas, colon, and liver. Chronic inflammation has been linked to higher risk of developing cancers such as bladder, esophageal, ovarian, prostate, or thyroid cancer [4]. Inflammatory cells and mediators of inflammation are present in the environment of most tumors, irrespective of the etiology of the tumor. Moreover, in some types of cancer, oncogenic changes may create an inflammatory microenvironment that promotes the development of tumors [3].

The main function of vitamin D is to regulate calcium and phosphate homeostasis [5]. However, outside of mineral ion homeostasis, it also modulates the adaptive and innate immune system [6–8] (see also Chapters 94–96) and has cancer-preventive and therapeutic actions in an endocrine, paracrine, and autocrine fashion [9,10]. Therefore, it could become an ideal preventive/therapeutic agent in inflammation-associated cancer.

This chapter systematically explores the role of vitamin D in inflammation-associated cancer, focusing specifically on cancers of the colon, prostate, breast, pancreas, and liver.

## 2. Vitamin D and the vitamin D system

Vitamin D<sub>3</sub> is synthesized in the skin from 7-dehydrocholesterol after exposure to UVB radiation or is obtained through the diet. Vitamin D<sub>3</sub> is subsequently transported to the liver by the vitamin D-binding protein (DBP), where it is converted into its main circulating form 25-hydroxyvitamin D<sub>3</sub> (25(OH)D<sub>3</sub>) through hydroxylation on position C-25 by cytochrome P450 (CYP) enzymes with 25-hydroxylase activity [11]. Generally, 25(OH)D<sub>3</sub> concentrations lower than 50 nmol/L are associated with vitamin D deficiency, and serum levels below 75 nmol/L 25(OH)D<sub>3</sub> are indicators of vitamin D insufficiency [12]. 1,25-Dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>), the most active vitamin D metabolite, is synthesized from 25(OH)D<sub>3</sub>, through 1 $\alpha$ -hydroxylation by 25-hydroxyvitamin D 1 $\alpha$ -hydroxylase (CYP27B1) mainly in the kidney, but also in other tissues. 1,25(OH)<sub>2</sub>D<sub>3</sub>, bound to its cognate receptor, the transcription factor vitamin D receptor (VDR), regulates a plethora of different cellular processes [10,13]. VDR is expressed ubiquitously in most human and animal tissues, rendering these tissues as potential targets for 1,25(OH)<sub>2</sub>D<sub>3</sub>. For a more detailed description, see [Chapters 10–13](#).

Apart from its classical role in calcium metabolism and in bone health, 1,25(OH)<sub>2</sub>D<sub>3</sub> is involved in the regulation of numerous signaling pathways [14,15]. Its activity correlates with the induction of differentiation in normal cells and inhibition of proliferation, angiogenesis, activation of apoptosis, repression of invasion, and metastasis in tumor cells, resulting in inhibition of tumor growth and even in tumor regression [9,16–18].

One of the best understood extra-skeletal functions of vitamin D is its immune-regulatory function. Vitamin D has also antimicrobial and anti-inflammatory effects [19] (see [Chapter 94](#)). 1,25(OH)<sub>2</sub>D<sub>3</sub> induces the expression of specific genes of the innate immune system, such as cytokines, pattern recognition receptors, defensins, and other antimicrobial peptides. It also regulates the adaptive immune system by modulating the activity of T cells [20,21] (see [Chapter 96](#)). The capacity of vitamin D to inhibit inflammation also contributes to its anti-tumorigenic effect, as chronic inflammation is a major determinant of several cancers [22], as mentioned before. Vitamin D has anticancer properties in a large variety of cancers, being most effective in colorectal [23–26] ([Chapter 89](#)), breast [27–29] ([Chapter 88](#)), and prostate cancers [30–32] ([Chapter 91](#)). In some cancers,

aberrant expression of components of the vitamin D system may impede the effect of 1,25(OH)<sub>2</sub>D<sub>3</sub>. Numerous preclinical studies support the association between vitamin D supplementation and prevention from the development and progression of different malignancies [16,33,34]. However, human clinical trials are still inconsistent, and the resulting data are incomplete and controversial [13,35–38].

## 3. Inflammation

Inflammation is a very complex process that accompanies a severe disturbance in tissue homeostasis as result of multiple different causes such as infection, stress, smoking, obesity, or exposure to mechanical or chemical contaminant agents that trigger the activation of the innate and adaptive immune system. Under physiological conditions, inflammation is a protective, self-limiting response to infectious agents and to tissue injury. Its main role is elimination of pathogens and the support of tissue regeneration [39]. Chronic inflammation is considered the “common soil” for multifactorial diseases, such as asthma, type 2 diabetes, rheumatic disorders, and several cancers [3,22,40]. Indeed, inflammation is frequently involved in tumor progression—therefore, Hanahan and Weinberg [1] added inflammation to the hallmarks of cancer.

### 3.1 Main characteristics of inflammation

The inflammatory response has four main components: (1) the inducers of inflammation (e.g., bacteria, viruses, irritants such as asbestos, chemicals, etc.), (2) the sensors recognizing inflammation (e.g., Toll-like and NOD-like receptors), (3) the mediators of inflammation (e.g., pro-inflammatory chemokines, cytokines, prostaglandins [PG]), and (4) the target tissues [39].

Some of the viral and bacterial inducers of inflammation are considered to be associated with 15%–25% of the cancers worldwide, e.g., cervical and hepatocellular carcinoma, or some forms of gastric cancer [41]. The sensors and mediators of inflammation are also important constituents of the tumor microenvironment. In some cancers, the inflammation precedes the malignant transformation (extrinsic process), while in other types of cancer, oncogenic changes induce the inflammatory environment that promotes tumorigenesis (intrinsic process) [42]. High levels of inflammatory cytokines in tumors are also indicators of poor prognosis.

The acute and chronic inflammatory response is driven by different subpopulations of immune cells. The innate immune system (monocytes, macrophages, dendritic cells, mast cells) is responsible for the acute

response. Its failure to eradicate the acute inflammation leads to chronic inflammation, a process involving the adaptive immune system: the T and B lymphocytes. The T lymphocyte population consists of several subgroups, comprising the cytotoxic CD8<sup>+</sup> T cells, T helper cells (Th), regulatory T cells (Treg),  $\gamma\delta$  T cells, memory cells, and natural killer cells [8]. The Th cells are considered either pro-inflammatory (Th1 or Th17) or anti-inflammatory (Th2) [2,43]. Tregs reduce proliferation of the effector cells and are involved in tolerogenic processes [2,8].

In most tissues, a few major pathways (such as NF- $\kappa$ B, STAT3, COX-2/PGE<sub>2</sub>, Wnt/ $\beta$ -catenin) orchestrate the inflammatory process. Inappropriately activated nuclear factor  $\kappa$ B (NF- $\kappa$ B) and tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) are considered as major mediators of inflammation [3,44]. Inflammatory cytokines secreted by the immune cells or the inflamed cells activate the transcription factors NF- $\kappa$ B and signal transducer and activator of transcription 3 (STAT3) in both the immune cells and epithelial tissue. NF- $\kappa$ B and STAT3 play an important role also in tumorigenesis, among others, by upregulation of the cyclooxygenase 2 (COX-2)/prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) signaling. COX-2/PGE<sub>2</sub> signaling is often deregulated in inflammation-associated tumorigenesis [45,46], as are the p38 and the stress-induced kinase pathways (ERK/MAPK) [19]. Wnt/ $\beta$ -catenin signaling maintains tissue homeostasis and is responsible for tissue regeneration after damage [47,48]. This pathway is deregulated in ~53% of IBD patients and is one of the most frequently mutated pathways in sporadic colorectal tumors [49].

### 3.2 Vitamin D and inflammation

Studies conducted on cell lines and observational studies demonstrated the inhibitory role of vitamin D in the inflammatory process; however, the clinical trials to confirm the correlation between vitamin D and inflammatory markers are still inconsistent [50–52].

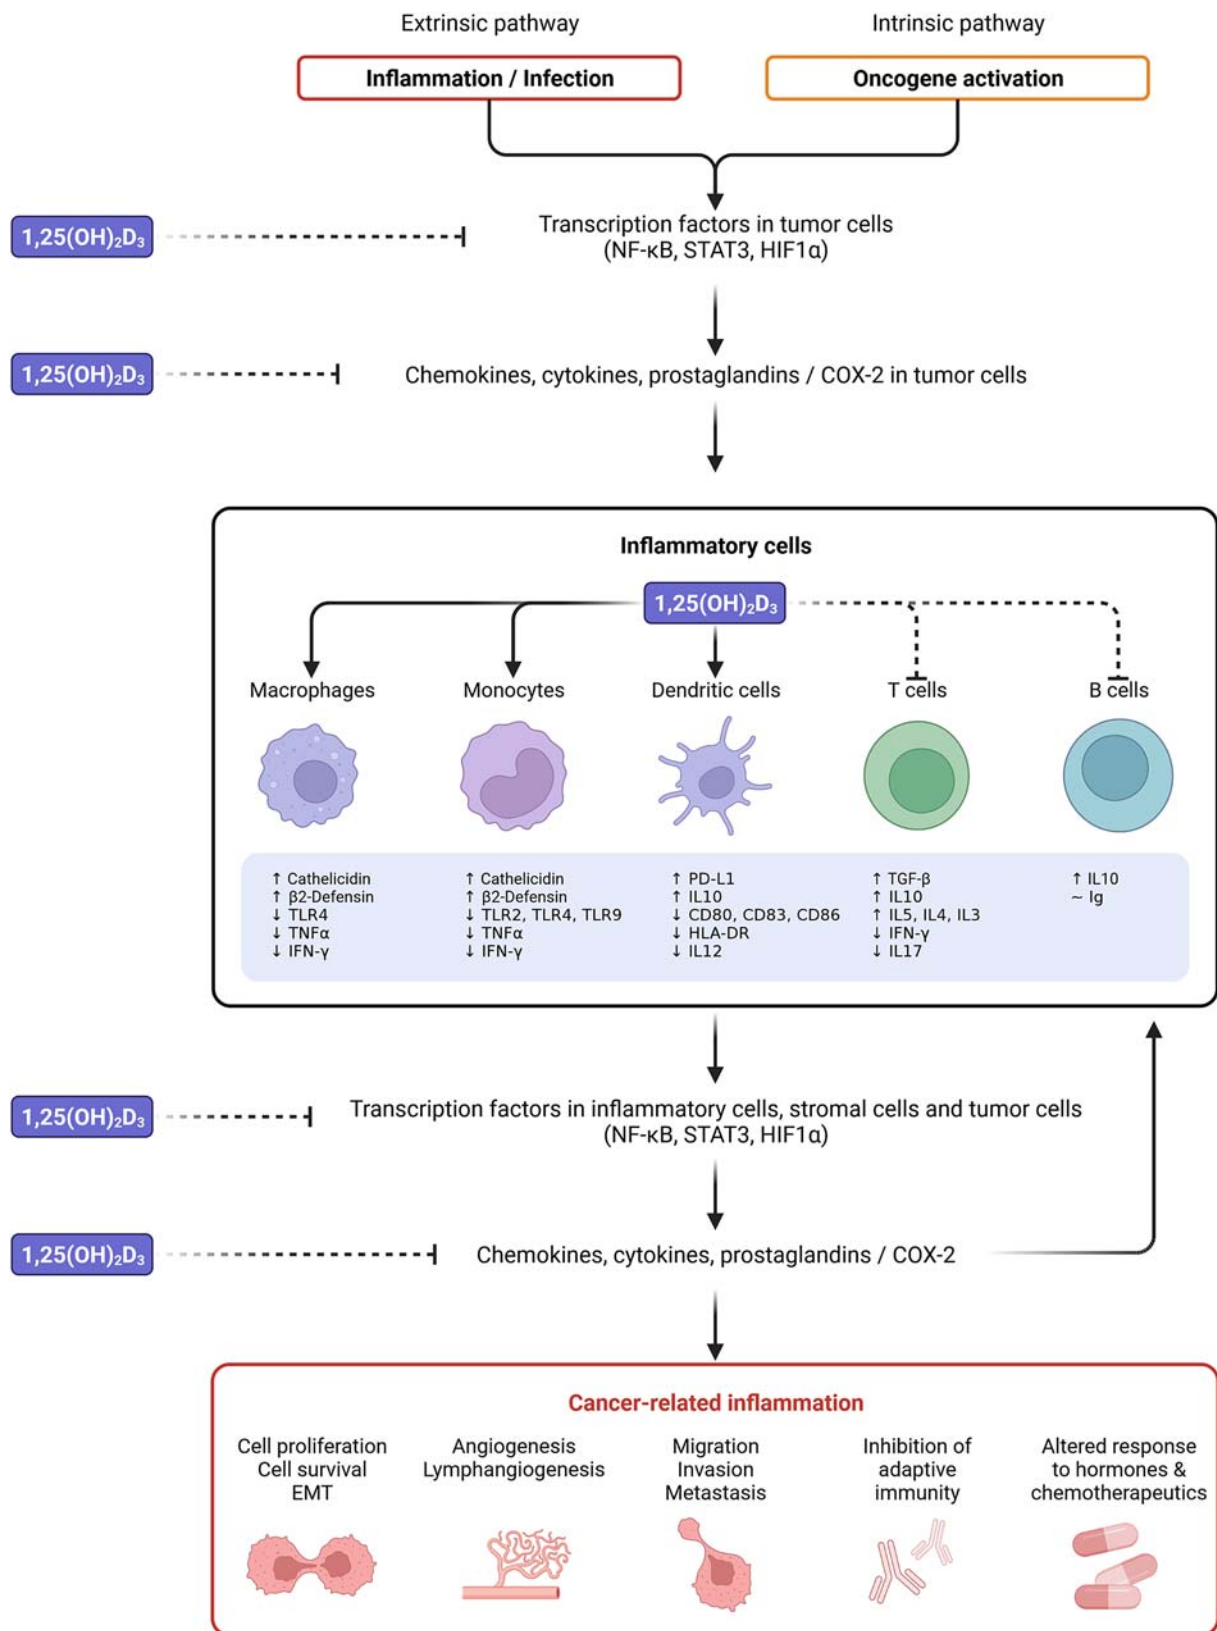

VDR and the vitamin D metabolizing enzymes are expressed in both the cells of the innate and the adaptive immune system, such as dendritic cells, monocytes/macrophages, in T and B cells, and in the cells of the target tissues (see Fig. 87.1 and also Chapters 94–96). Cells of the immune system produce 1,25(OH)<sub>2</sub>D<sub>3</sub> that exerts immunomodulatory effects, regulating innate and adaptive immune responses in a cell type-dependent and species-dependent manner [20,53]. Vitamin D and its metabolites are important players in regulation of different inflammation-related molecular pathways [54,55]; they affect all four components of the inflammatory response.

#### 3.2.1 Effect of vitamin D on inducers of inflammation: antimicrobial effects of vitamin D

Although the beneficial effect of sun for patients with different infections—both viral and bacterial—was recognized in the past, it was only recently that the molecular mechanism behind the observed antimicrobial effects of vitamin D and the role of the vitamin D target gene cathelicidin was elucidated, at least partially [56–58]. The human cationic antimicrobial protein (hCAP-18), belonging to the cathelicidin family of antimicrobial proteins, was identified first in 1995 [59]. hCAP-18 has broad antimicrobial activity against several pathogens, e.g. *Mycobacterium tuberculosis* [57] and *Staphylococcus aureus* [60]. One of the mechanisms of action of hCAP-18 is to trigger the activation of autophagy [61]. During infections caused by pathogens, 1,25(OH)<sub>2</sub>D<sub>3</sub> increased the antimicrobial capacities of antigen presenting cells—macrophages and monocytes, as well as of epithelial cells of the lung and intestines, placental trophoblasts, and keratinocytes, by inducing hCAP-18 expression [57]. In the monocyte/macrophage lineage, interferon gamma (IFN- $\gamma$ ) stimulated antimicrobial activity by inducing phagosome maturation, autophagolysosomal fusion, and autophagy through a 1,25(OH)<sub>2</sub>D<sub>3</sub>-dependent pathway [62]. 1,25(OH)<sub>2</sub>D<sub>3</sub> activated phagocytosis in monocytes and macrophages of pulmonary tuberculosis patients, by upregulating mannose receptor and the expression of autophagy genes ATG5 and BECN1 [63].

Differentiation of human monocytes toward dendritic cells under the influence of 1,25(OH)<sub>2</sub>D<sub>3</sub> and phenylbutyrate enhanced antimicrobial properties of the dendritic cells by stimulating induction of cathelicidin expression and ROS levels, thus increasing their capacity of killing *Staphylococcus aureus* [64]. In addition, patients with infectious diseases often have inadequate vitamin D levels. Chronic hepatitis C virus (HCV) infection was associated with vitamin D deficiency [65]. Chronic hepatitis B (CHB) patients with vitamin D deficiency had significantly higher HB virus replication than CHB patients with normal 25(OH)D<sub>3</sub> levels [66] (see Chapter 95). Moreover, vitamin D supplementation reduced disease severity and mortality from and infection with SARS-2/COVID-19 [67–70] (see also Chapter 99).

Not only does vitamin D affect microorganisms, but also the microorganisms affect expression, localization, and activity of VDR and the vitamin D system. In human fibroblasts the cytomegalovirus (CMV) downregulated VDR and CYP24A1 expression and upregulated CYP27B1 mRNA levels, inhibiting the antiviral effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> [71,72]. Colonization of colon cancer cells with *Salmonella typhimurium* upregulated VDR

**FIGURE 87.1** Effects of 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>) on the inflammatory cells and cancer-related inflammation. Both extrinsic (represented by inflammation or infection) and intrinsic pathways (activated by genetic events such as activation of oncogenes) result in the activation of transcription factors in tumor cells that stimulate the production of proinflammatory chemokines, cytokines, and prostaglandins.

expression and transcriptional activity. Commensal enteric bacteria influenced VDR distribution in the colonic crypt [73].

### 3.2.2 Effect of vitamin D on receptors and mediators of inflammation

Vitamin D modulates the expression of receptors and mediators of inflammation (Fig. 87.2) in a complex, and cell- and tissue-dependent manner. Treatment of human keratinocytes with  $1,25(\text{OH})_2\text{D}_3$ -induced expression of CD14, a coreceptor of TLR4, and of the Toll-like receptor TLR2 [74], involved also in autophagy [75]. In monocytes,  $1,25(\text{OH})_2\text{D}_3$  suppressed expression of TLR2, TLR4, and TLR9 and TLR9-dependent upregulation of IL6 production, confirming the beneficial role of vitamin D supplementation in patients with autoimmune diseases with elevated IL6 serum levels [76].  $1,25(\text{OH})_2\text{D}_3$  inhibited the production of the proinflammatory cytokines IL17, IL21, and IFN- $\gamma$  and was associated with high expression of CTLA-4 and FoxP3 and upregulation of IL10, stimulating a regulatory response in T cells [77].

VDR inhibits NF- $\kappa$ B activity on multiple levels (Figs. 87.2 and 87.3). It was shown to prevent phosphorylation of the NF- $\kappa$ B subunit p65 and to inhibit its nuclear translocation by binding directly to p65 [73]. VDR prevented the phosphorylation of the inhibitor of NF- $\kappa$ B (I $\kappa$ B) and the release of NF- $\kappa$ B from I $\kappa$ B inhibition by binding to I $\kappa$ B kinase- $\beta$  (IKK $\beta$ ) [78].  $1,25(\text{OH})_2\text{D}_3$  extended the half-life of IKK $\beta$  mRNA [79] and inhibited COX-2 expression and subsequent PG synthesis in a dose-dependent manner [80]. Vitamin D stimulated the synthesis of antiinflammatory cytokines such as IL10 and TGF $\beta$  as well. IL10, released by Th2 cells, B cells, and macrophages, prevents host immune response to pathogens, while TGF $\beta$  is a mediator of the immunosuppressive function of Tregs [81,82].

### 3.2.3 Effect of vitamin D on immune cells

CD4<sup>+</sup> T cells of mice fed with  $1,25(\text{OH})_2\text{D}_3$ -supplemented diet had low levels of IL17, and the ability of the dendritic cells to mediate T cell transformation toward Th17 phenotype was reduced [83]. In nonobese diabetic mice,  $1,25(\text{OH})_2\text{D}_3$  suppressed proinflammatory TNF $\alpha$ , iNOS, and IL12p40 expression and inhibited the expression of chemokines with T cell recruiting properties, such as CXCL9, CXCL10, and CXCL11, in an IL10-dependent manner [84].

Vitamin D is able to regulate both the innate and the adaptive immune system (Fig. 87.1), although its primary role is strengthening the immediate response to infections. It enhances the antipathogenic actions of the innate immune system and regulates proliferation and differentiation of the adaptive immune system (see more detailed information in Chapters 94–96). The effect of vitamin D on immune cells is very complex, depending on the activation status of the immune cells [85]. VDR-bound  $1,25(\text{OH})_2\text{D}_3$  affects gene transcription either directly or indirectly, by modulating the epigenome [86].

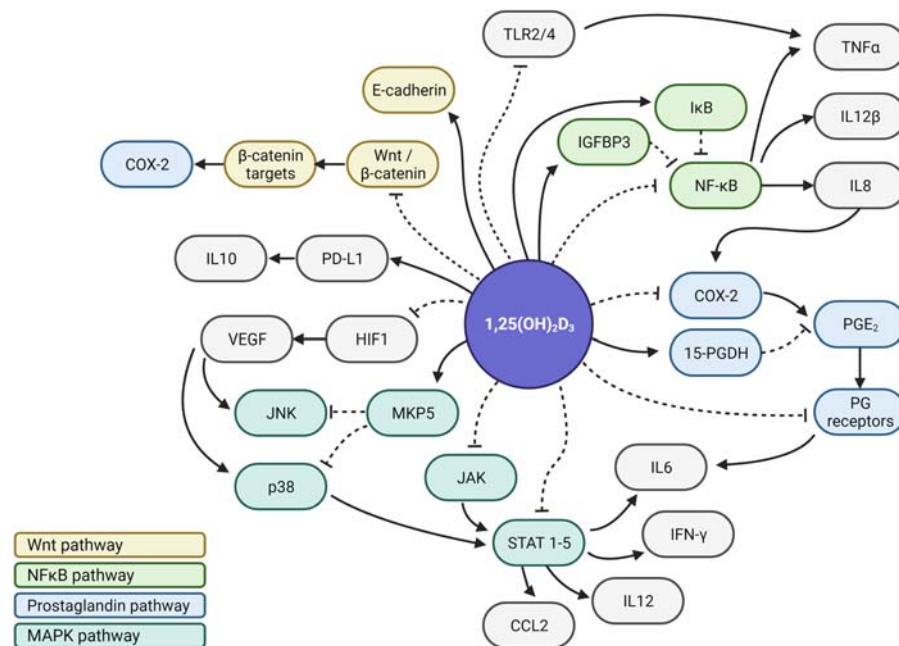

Naïve T cells have very low levels of VDR, but upon activation of the T cells, VDR is upregulated [51]. Both the systemic  $1,25(\text{OH})_2\text{D}_3$  and the  $1,25(\text{OH})_2\text{D}_3$  synthesized locally in T cells, monocytes, or dendritic cells, can affect T cell response either directly or indirectly, by modulating antigen presentation of dendritic cells to T cells [8]. Vitamin D is also a major regulator of T cell proliferation [87]. In immune-mediated diseases,  $1,25(\text{OH})_2\text{D}_3$  inhibited T cell proliferation, reduced inflammatory responses of Th1 and Th17 cells, while promoting the Th2 subtype, important for tissue repair [51]. This change is characterized by a switch in the cytokine profile. Interestingly, in infectious diseases where the Th1 and Th17 responses are necessary for the host response, this effect was not observed [88]. Regulatory T cell (Tregs)—lymphocytes that inhibit the immune response of other types of T cells—were induced by  $1,25(\text{OH})_2\text{D}_3$  in patients with renal disease, explaining the tolerogenic effect of vitamin D in renal transplant patients [89] (see also Chapter 74).

B cells play a crucial role in autoimmune diseases, such as rheumatoid arthritis, lupus erythematosus or type 1 diabetes, due to the production of autoantibodies. The modulatory effect of  $1,25(\text{OH})_2\text{D}_3$  on B cell activity is important in the autoimmune diseases mediated by B cells. In B cells,  $1,25(\text{OH})_2\text{D}_3$  suppressed immunoglobulin secretion and cell proliferation, and induced p27 expression and apoptosis, repressing naïve B cell differentiation and maturation to memory B and plasma cells [90]. High serum vitamin D levels were inversely associated with memory B cells, while vitamin D<sub>3</sub> restriction specifically promoted memory B cell development, accompanied by elevated levels of serum IgM, IgG1, IgG3, and anti-dsDNA IgG in a mouse model of systemic lupus [91].

Apart from their antigenic properties, to capture, process, and present antigens to adaptive immune cells

These activate different inflammatory cells, eventually resulting in an inflammatory microenvironment in tumors.  $1,25(\text{OH})_2\text{D}_3$  suppresses both the transcription factors and the production of chemokines, cytokines, and prostaglandins. It regulates activation and activity of inflammatory cells resulting in inhibition of cancer-related inflammation. *Solid arrows* indicate effect, *dotted lines* indicate inhibition. CD, cluster of differentiation; COX-2, cyclooxygenase 2; EMT, epithelial-to-mesenchymal transition; HIF-1, hypoxia-inducible factor 1; HLA-DR, human leukocyte antigen DR; IFN $\gamma$ , interferon gamma; Ig, immunoglobulins; IL, interleukin; NF- $\kappa$ B, nuclear factor kappa B; PD-L1, programmed cell death ligand 1; STAT3, signal transducer and activator of transcription 3; TGF $\beta$ , transforming growth factor beta; TLR, Toll-like receptor; TNF $\alpha$ , tumor necrosis factor alpha. **FIGURE 87.2** Effect of  $1,25(\text{OH})_2\text{D}_3$  on receptors and mediators of inflammation-associated cancer.  $1,25(\text{OH})_2\text{D}_3$  inhibits the synthesis and activity of prostaglandins (PG), stimulating 15-PGDH expression leading to PG inactivation, suppressing COX-2 expression inhibiting the synthesis of PGs, and downregulating PG receptors.  $1,25(\text{OH})_2\text{D}_3$  inhibits STAT1-5 signaling, induces MKP5 expression that suppresses p38 activation resulting in decreased IL6 levels. By inhibiting NF- $\kappa$ B expression, either directly or by activating IGFBP3,  $1,25(\text{OH})_2\text{D}_3$  has a suppressive effect on proinflammatory cytokines, such as TNF $\alpha$ , IL12 $\beta$ , and IL8. Expression of TNF $\alpha$  is downregulated by suppressing TLR2 and TLR4.  $1,25(\text{OH})_2\text{D}_3$  inhibits HIF1 that leads to downregulation of VEGF and inhibition of the JNK and p38 pathways.  $1,25(\text{OH})_2\text{D}_3$  induces E cadherin expression and blocks  $\beta$  catenin nuclear activity, by inhibiting Wnt/ $\beta$  catenin signaling pathway. Arrows indicate activation, dotted lines indicate inhibition. CCL2, C-C motif chemokine ligand 2; HIF1, hypoxia-inducible factor 1; IFN- $\gamma$ , interferon gamma; IGFBP3, insulin-like growth factor-binding protein 3; I $\kappa$ B, inhibitor of NF- $\kappa$ B; IL, interleukin; JNK, c-Jun N-terminal kinase; MKP5, mitogen-activated protein kinase phosphatase 5; NF- $\kappa$ B, nuclear factor kappa B; PGE $_2$ , prostaglandin E $_2$ ; STAT1-5, signal transducer and activator of transcription 1–5; TLR, Toll-like receptor; TNF $\alpha$ , tumor necrosis factor alpha; VEGF, vascular endothelial growth factor. and mediate their polarization into effector cells, mature dendritic cells have the capacity to stimulate T cell activity. Exposure of mouse bone marrow–derived dendritic cells to  $1,25(\text{OH})_2\text{D}_3$  prevented their maturation and maintained a tolerogenic state that encouraged activation of the Treg phenotype.  $1,25(\text{OH})_2\text{D}_3$ -treated dendritic cells inhibited T cell proliferation and increased expression of the tolerogenic cytokines TGF $\beta$  and IL10 [92], and increased the expression of programmed death ligand 1 (PD-L1) [93]. Vitamin D signaling is essential also for T cell homing to the gastrointestinal tract. Defects of T cell homing might be one of the reasons for the increased inflammatory potential observed in the gastrointestinal tract of VDR knockout (VDR $^{-/-}$ ) mice. These animals express lower levels of the noncytotoxic CD8 $^{+}$  T cell variant CD8 $\alpha\alpha$  that seems to suppress gastrointestinal inflammation [94,95].

### 3.3 Effect of vitamin D in inflammatory diseases

Vitamin D deficiency is prevalent in several inflammatory and autoimmune diseases, such as type

1 diabetes, asthma, rheumatoid disorders, inflammatory bowel disease (IBD), lupus, and multiple sclerosis [96]. It has been suggested that the environmental factor that most strongly influences development of autoimmune diseases is vitamin D [97]. Genetic linkage analysis has revealed that rare inactivating mutations of *CYP27B1* seem to play a causative role in the development of multiple sclerosis [98]. Genome-wide association studies provided evidence that vitamin D deficiency probably plays a causal role in the pathogenesis of type 1 diabetes. Different inherited polymorphisms in the genes of the vitamin D system are associated with predisposition to type 1 diabetes [99]; e.g., low  $25(\text{OH})\text{D}_3$  serum levels due to the rs10741657G polymorphism of *CYP2R1* were associated with high incidence of type 1 diabetes [100,101]. A metaanalysis found that vitamin D reduced disease activity index in systemic lupus erythematosus patients [102].

Low vitamin D levels are prevalent also in IBD patients [103]. IBD, with its two forms ulcerative colitis (UC) and Crohn's disease (CD), is often a major risk factor of colorectal cancer (CRC). High doses of vitamin D

**FIGURE 87.3 Interactions of 1,25(OH)<sub>2</sub>D<sub>3</sub> with the signaling pathways associated with inflammatory bowel disease and colorectal cancer.** COX-2 expression is activated by inflammatory inducers (TNFα, PAMPs) through TNFR or TLR and activation of NF-κB or by mediators of proliferation (Wnt, EGF). Interaction between 1,25(OH)<sub>2</sub>D<sub>3</sub> and VDR regulates proinflammatory TLR expression. Activated VDR suppresses NF-κB either directly or by increasing cytoplasmic glutathione levels that inhibit ROS expression. Inhibition of the NF-κB signaling pathway reduces the expression of proinflammatory mediators (TNFα, IL6, CCL2). Activated EGFR suppresses expression of 15-PGDH, the enzyme catabolizing PGE<sub>2</sub>, by inducing SNAI1. The intracellular production of PGE<sub>2</sub> from AA by COX-2 is highly stimulated in inflammatory bowel disease. PGE<sub>2</sub> is transported out of the cell by MRP4, while into the cell by PGT. PGE<sub>2</sub> binds the prostaglandin EP and stimulates signaling. 1,25(OH)<sub>2</sub>D<sub>3</sub>-bound VDR blocks PGE<sub>2</sub> accumulation by inhibition of EP2 and induction of 15-PGDH expression. 1,25(OH)<sub>2</sub>D<sub>3</sub> also suppresses EGFR expression. Solid arrows indicate activation, and dotted lines indicate inhibition. Gradient arrows indicate translocation. 15-PGDH, 15-hydroxyprostaglandin dehydrogenase; COX-2, cyclooxygenase 2; EGF, epidermal growth factor; EGFR, epidermal growth factor receptor; EP, prostaglandin E receptor; IL6, interleukin 6; CCL2, C–C motif chemokine ligand 2; MRP4, multidrug resistance–associated protein 4; NF-κB, nuclear factor kappa B; PAMP, pathogen-associated molecular pattern; PGE<sub>2</sub>, prostaglandin E<sub>2</sub>; PGT, prostaglandin transporter; ROS, reactive oxygen species; SNAI1, SNAIL drosophila homolog of 1; TLR, Toll-like receptor; TNFα, tumor necrosis factor alpha; TNFR, tumor necrosis factor receptor; VDR, vitamin D receptor. Figure created with Biorender.com.

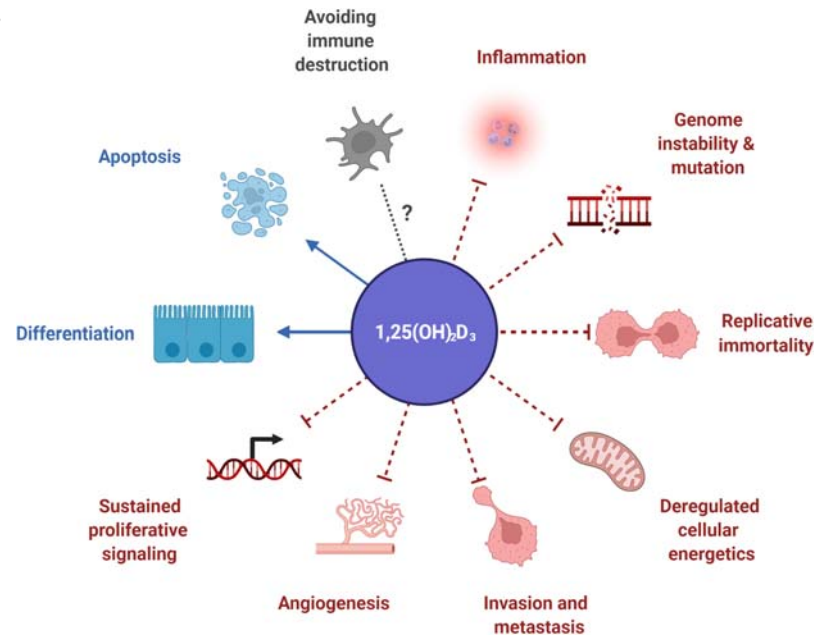

or normalization of serum vitamin D levels led to remission and reduced risk for surgery in patients with mild to moderate Crohn's disease [104–107]. In animal models of IBD, vitamin D prevented or ameliorated inflammation and clinical disease [108–110].

To summarize, inflammation is caused by a variety of factors and is associated with a wide range of diseases, including cancers and autoimmune disorders. VDR and the vitamin D metabolizing enzymes are expressed almost ubiquitously in the innate and adaptive immune system. The interaction between vitamin D and inflammation is complex. On the one hand, vitamin D inhibits inflammation; on the other hand, inflammation affects vitamin D metabolism and signaling. The potential of vitamin D to inhibit inflammation depends on the disease characteristics and on the levels of the vitamin D metabolites.

#### 4. Inflammation-associated cancer

Inflammation and “evading immune destruction” were eventually added to the hallmarks of cancer [1]. The hallmarks of inflammation-related cancer include the presence of inflammatory cells and inflammatory mediators in the tumor, activated tissue remodeling and angiogenesis, similar to that seen in chronic inflammatory responses, and tissue repair [42]. The active vitamin D metabolite 1,25(OH)<sub>2</sub>D<sub>3</sub> affects most cancer hallmarks. It inhibits proliferation, angiogenesis, invasion, and metastasis [13], alters cellular metabolism, induces differentiation and apoptosis, and inhibits protumorigenic inflammation [9,111] (Fig. 87.4). Main drivers of cancer are highly active oncogenes in parallel with silenced tumor suppressors. Many of the oncogenes upregulated in several cancers, such as growth

**FIGURE 87.4** Effect of  $1,25(\text{OH})_2\text{D}_3$  on the hallmarks of cancer. Figure created with Biorender.com.

factors, growth factor receptors, kinases, and transcription factors, are also involved in the inflammatory process.

The normal inflammatory mechanisms, essential for tissue regeneration and the fight against infections, resolve after healing, but chronic inflammation can promote tumorigenesis, due to a feed-forward loop of inflammatory cell recruitment and inflammation-induced signaling. Around 15%–20% of all cancers are preceded by chronic inflammation or infection; e.g., IBD, chronic hepatitis, or pancreatitis, leading to CRC, liver, or pancreatic cancer, respectively [2]. The immune system, as part of the tumor microenvironment, can act both antitumorigenic, enabling immune-surveillance, and protumorigenic, blocking antitumor immunity and secreting tumor-promoting signals [2]. “Hot”, or immunogenic tumors, show signs of inflammation and are usually responsive to cancer immunotherapy. In inflammation-associated cancer, numerous pathways are active that suppress antitumor immunity, supporting cancer-promoting inflammation. A central question is, how to switch the tumor-promoting immune-suppressive microenvironment to a tumor-destroying state [2].

The role of vitamin D in modulating the immune surroundings in cancer is unclear. Ample evidence suggests that it promotes antitumorigenic phenotype of cancer cells and the cancer-associated microenvironment, but it also induces expression of PD-L1 the ligand of the immune-checkpoint inhibitor (programmed cell death protein 1), which could lead to evasion from immune-surveillance [112]. In a recent study, however, high

serum PD-L1 levels correlated significantly with low levels of vitamin D [113]. There are no clear-cut studies suggesting that vitamin D enables evasion from immune-surveillance. There is some evidence [114] that similarly to the Th1 and Th17 response regulation in infectious diseases [88], in tumors, vitamin D supports immune surveillance [114]. Morita et al. found that in patients with digestive tract cancers, vitamin D supplementation upregulated PD-L1 levels only in patients with lowest PD-L1 levels (quintile Q1), but reduced PD-L1 expression in patients with the highest quintile (Q5). In this group of patients (Q5), vitamin D supplementation reduced also the risk of relapse and mortality [114]. The vitamin D target gene IL10 is able, on the one hand, to stimulate antitumor immunity and, on the other, to inhibit tumor-associated inflammation [115]. Additionally, vitamin D inhibits epithelial-to-mesenchymal transition (EMT) [116], a process often supported by inflammatory markers and needed for invasion [117].

In the following sections, we will focus on the effect of vitamin D on the pathways that link inflammation and tumorigenesis.

#### 4.1 Key factors in inflammation-associated cancer

The interplay between inflammation and cancer is complex and affects the progression of a wide variety of solid tumors [118,119]. Inflammation and cancer are linked by two major pathways: an extrinsic pathway, driven by infections or inflammatory conditions that

enhance cancer risk and an intrinsic pathway, driven by genetic alterations that cause both transformation and inflammation [42]. Extrinsic circumstances, such as chronic inflammation in several tissues (colon, prostate, pancreas, liver), create conditions that favor promotion and progression of cancer. The intrinsic pathway links oncogene activation and/or tumor suppressor silencing with local inflammation. In transformed cells, inflammatory responses sustain survival and proliferation, leading to tumor promotion [120]. It has been hypothesized that oncogenes, regardless of their molecular class, coordinate inflammatory transcriptional programs that are linked to angiogenesis and to recruitment of cells of the myelomonocytic lineage [42]. Usually, both the intrinsic and the extrinsic pathways are needed to promote tumor formation (Fig. 87.1).

Among the key intrinsic factors triggering inflammation-associated cancer are transcription factors such as NF- $\kappa$ B and STAT3, as well as inflammatory cytokines (e.g., IL1 $\beta$ , IL6, IL17, IL23, TNF $\alpha$ , IFN- $\gamma$ ), chemokines (e.g., IL8, CCL2, CCL5), prostaglandins (PGE<sub>2</sub>, PGF<sub>2 $\alpha$</sub> ), survival molecules (survivin, Bcl-2, Bcl-xl), and molecules linked to metastasis (MMPs, VEGF) [22,119,121].

#### 4.1.1 Nuclear factor $\kappa$ B pathway

NF- $\kappa$ B, the key coordinator of inflammation, is also considered a major endogenous tumor promoter [122]. It has several subunits, the classical p50, p65, and the nonclassical p52 and Rel-B [123]. I $\kappa$ B, the inhibitor of NF- $\kappa$ B, sequesters the subunits p50 and p65 in the cytoplasm. I $\kappa$ B is degraded upon phosphorylation by IKK $\beta$  and subsequent ubiquitination, enabling translocation of p50 and p65 into the nucleus, where NF- $\kappa$ B induces transcription of both pro- and antiinflammatory cytokines (e.g., IL1, IL4, IL6, IL10, IL12, IL17, IL23), chemokines (e.g., IL8, CCL2, CXCL12), antiapoptotic molecules (Bcl-2, Bcl-xl, survivin), matrix metalloproteinases (MMPs), and adhesion molecules (VEGF, TWIST, CXCR4) [124]. In tumors, NF- $\kappa$ B activation is mainly driven by inflammatory cytokines within the tumor microenvironment [125] and leads to transcription of inflammatory cytokines, COX-2, inducible nitric oxide synthase (iNOS), adhesion molecules, angiogenic factors, and antiapoptotic genes [44]. NF- $\kappa$ B is important also in determining the balance between the tumor promoting and antitumor properties of macrophages.

#### 4.1.2 Signal transducers and activators of transcription 3 pathway

STAT3 is a pleiotropic transcription factor, activated in both immune and tumor cells. It is activated through phosphorylation by numerous cytokine and growth factor receptors. STAT3 signaling is one of the major intrinsic inflammatory pathways involved also in

tumorigenesis [126,127]. In inflammation-driven cancers, STAT3 is constitutively activated by high levels of the proinflammatory cytokine IL6 in a feed-forward loop with itself and NF- $\kappa$ B [126,128]. It increases the capacity of tumors to evade the immune system, induces oncogenesis and cancer cell stemness, and inhibits apoptosis [119,129–131].

#### 4.1.3 Prostaglandin pathway

Activation of PG signaling is an early event during progression from inflammation to malignancy [19,54,132]. PGs are bioactive lipids derived from arachidonic acid. The rate-limiting enzyme in PG synthesis is the PG-endoperoxide synthase, also known as cyclooxygenase (COX). COX-1 is constitutively expressed, while expression of the inducible isoform COX-2 is rapidly induced by growth factors, cytokines, and tumor promoters and is often overexpressed in tumors [133]. 15-Hydroxyprostaglandin dehydrogenase (15-PGDH) is the enzyme responsible for the catabolism of PGs [134]. COX-2 is expressed both in epithelial cells and in infiltrating macrophages, and COX-2/PGE<sub>2</sub> signaling is essential in promoting tumor progression and encouraging metastatic spread [132,135]. COX-2 is upregulated in inflamed tissues such as the mucosa of IBD patients and in colorectal tumors, while 15-PGDH expression is reduced [136–138]. High COX-2 levels were seen in prostate, in areas of proliferative inflammatory atrophy (PIA) [139]. In prostate tumors, COX-2 expression is a prognostic factor for high-risk disease [140,141]. In breast cancer, COX-2 levels were high in aggressive tumors [142]. Chemotherapy often induces COX-2/PGE<sub>2</sub> signaling, which then impairs the efficacy of immunotherapies [143]. Synthesis of PGs at sites of infiltration of inflammatory cells in tumors contributes to tumor progression by stimulating expression of genes involved in proliferation.

#### 4.1.4 Wnt/ $\beta$ -catenin pathway

Canonical Wnt signaling is mediated by a complex between the frizzled receptor (FZD) and its coreceptor, the low-density lipoprotein receptor-related protein 5 or 6 (LRP5/6). In the absence of Wnt activators,  $\beta$ -catenin is bound and phosphorylated in a complex of proteins involving the scaffold protein axin2, adenomatous polyposis coli (APC), and the serine-threonine kinases CK-1 and GSK-3 $\beta$  for subsequent proteasomal degradation. Activation through Wnt ligands leads to nuclear translocation of  $\beta$ -catenin, association with the T cell factor/lymphoid enhancer factor (Tcf/Lef) transcription factors, and transcription of genes regulating among others proliferation, differentiation, tissue regeneration, and wound healing [144,145]. Aberrant activation of the Wnt/ $\beta$ -catenin pathway is one of

the first steps toward malignant transformation in sporadic CRC.

In numerous inflammation-associated cancers, there is a cross-talk between the Wnt/ $\beta$ -catenin pathway and the inflammatory cascade [47,48,146], partially through the NF- $\kappa$ B pathway [147,148]. Activation of Wnt/ $\beta$ -catenin signaling induces COX-2 in cancer cells. The resulting increase in PGE<sub>2</sub> triggers aberrant Wnt/ $\beta$ -catenin pathway and promotes inflammatory cancer progression, also by upregulating IL1 $\beta$  and IL8 secretion from macrophages [149]. The immune cells in the microenvironment of the tumors play an essential role in tumor development and metastasis. Tumor-associated fibroblasts (TAFs) are important sources of tumor-promoting chemokines, cytokines, and growth factors. Chemokines, their receptors, and cytokines coordinate the autocrine and paracrine interactions between neoplastic cells and TAFs. Coculture of tumor cells with macrophages increased the invasive capacity of tumor cells in an NF- $\kappa$ B- and TNF $\alpha$ -dependent manner, affecting their ability to colonize the metastatic niche [150].

## 4.2 Vitamin D and inflammation-associated cancer

Numerous epidemiological studies suggest that high levels of serum 25(OH)D<sub>3</sub> prevented the development of different cancers and increased the survival rate of patients [151–156]. Interventional studies, however, often failed to show such an effect for increased vitamin D<sub>3</sub> intake [157–159]. The reasons for the contradictory results of the interventional studies could be manifold, including individual differences in responsiveness to vitamin D<sub>3</sub>, insufficient dosage, inadequate duration of the intervention, and poor compliance. The antitumorogenic actions of vitamin D<sub>3</sub> were more convincing in animal studies [160,161], possibly due to the strictly controllable experimental conditions (“lifestyle,” diet) and the genetic homogeneity of the animals.

The strongest evidence on the protective role of high serum 25(OH)D<sub>3</sub> levels against different types of cancer was obtained in association with colon, prostate, and breast cancers (see more in Chapter 84).

### 4.2.1 Molecular pathways regulated by vitamin D in inflammation-associated cancer

Vitamin D prevents inflammation-associated cancers by regulating events downstream both the extrinsic and intrinsic pathways (Fig. 87.1). It ameliorates severity of chronic inflammations by regulating the innate and adaptive immune system [51]. Additionally, VDR-bound 1,25(OH)<sub>2</sub>D<sub>3</sub> modulates transcriptional activity of genes involved in proliferation, differentiation,

apoptosis, migration, and inflammation in an autocrine or paracrine way and regulates a complex network that controls both normal and malignant cell growth [9,10,13]. Both in inflammation and in many tumors, expression of the VDR, the synthesis, and the catabolism of vitamin D metabolites are altered, compromising 1,25(OH)<sub>2</sub>D<sub>3</sub> sensitivity and signaling [9]. The genes regulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> in tumors are only partially the same as the genes regulated in the corresponding normal tissue [162].

Vitamin D regulates all the major pathways driving inflammation-associated cancer, modulating both cancer-related and inflammation-related signaling (Figs. 87.1 and 87.3) [163]. Gene ontology analysis showed that in the leukemia cell line THP-1, the most significant processes regulated by the treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> were immune functions, such as neutrophil signaling and inflammatory responses [164]. The intrinsic pathway driven by the c-MYC oncogene was targeted by the growth inhibitory effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> [165]. Vitamin D prevented tumor angiogenesis by reducing expression of several angiogenic factors (VEGF, HIF-1, IL8). It suppressed PG synthesis and signaling and induced PG degradation. The dual phosphatase MKP5 dephosphorylates and thus inactivates several mitogen-activated kinases. Dephosphorylation of p38 leads to inhibition of proinflammatory cytokine (e.g., IL6) production. 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced MKP5 expression, leading to subsequent inhibition of the p38 signaling, inhibited invasion, and metastasis by preventing MMP9 upregulation. 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment modulated the RHO-ROCK pathway and increased E-cadherin expression (see for review: [13,19,166]).

### 4.2.2 Effect of vitamin D in inflammation-associated colorectal cancer

Inflammation is a major risk factor for CRC. Patients with inflammatory bowel diseases have a higher risk to develop gastrointestinal cancers depending on the type of IBD, location, and extent of the disease [167,168]. Diet and lifestyle contribute to the progression from IBD to cancer either directly, by affecting expression or activity of genes interacting with the inflammatory pathways, or indirectly, through their effect on the immune system and the microbiota [169–172].

Numerous molecular alterations responsible for development of sporadic CRC are also involved in colitis-associated colonic carcinogenesis, although some of the pathways are different, or are altered differently [170]. Comparing the genomic landscape of IBD-associated CRC (colitis-associated CRC, CAC) with that of sporadic colorectal tumors, Robles et al. [173] found similar mutations in the pathways triggered by PI3K, BRAF, ERBB2, and TGF $\beta$ . Some of the key mutations in sporadic colorectal tumors, e.g., KRAS

mutations were not common in CAC, suggesting differences in the etiology of IBD-associated CRC and that of sporadic CRC. In over 80% of sporadic colorectal tumors, the Wnt/ $\beta$ -catenin pathway is altered, mainly due to inactivating mutations of adenomatous polyposis coli (*APC*). In contrast, genes of the Wnt/ $\beta$ -catenin pathway were mutated only in about 53% of the CACs. However, most of the mutations were in the gene coding for the *SOX9* transcription factor and not in *APC* [173]. Another cause of the Wnt/ $\beta$ -catenin activation in CAC was the methylation-dependent silencing of Wnt inhibitors [174]. A further study found that mutations in *TP53*, *IDH1*, and *c-MYC* were much more frequent in CAC than in sporadic CRC [175]. Genetic alterations in genes associated with cell-to-cell communication were more prevalent in the IBD-associated tumors; furthermore, the Rho-Rac pathway was mutated in 50% of CAC tumors [173].

Vitamin D serves also as an immunoregulatory micro-nutrient, necessary for maintaining gut epithelial integrity, prevention of IBD, and inflammation-associated CRC (Fig. 87.3) [106,176,177]. IBD patients are very often vitamin D deficient [107], and the vitamin D system is often deregulated in the intestine of both IBD and in CRC patients. *VDR* expression is significantly lower in the intestines of IBD patients [178]. In patients with active CD, *VDR* expression levels are decreased in comparison with patients with quiescent disease and correlate inversely with inflammation [179,180]. *CYP27B1* protein expression is low in normal colonic mucosa. In chronically inflamed tissues, *CYP27B1* is upregulated as a defense mechanism to enhance tissue concentration of 1,25(OH) $_2$ D $_3$ . The 1260 TT polymorphism in *CYP27B1* gene was associated with higher calprotectin levels [181]. Adenomas and moderately differentiated adenocarcinomas also express high levels of *CYP27B1*, whereas in undifferentiated areas of high-grade tumors, *CYP27B1* is undetectable [182]. An active and functioning *CYP27B1*/*VDR* system in the colon is needed to prevent cancer-initiating COX-2 activity [183]. *VDR* expression is lost also in undifferentiated colorectal tumors, while the catabolizing *CYP24A1* is overexpressed [184–186]. In a xenograft model, overexpression of *CYP24A1* led to more aggressive tumors [187]. In African Americans, two SNPs (single-nucleotide polymorphisms) of *CYP24A1* correlated positively with CRC risk [188].

There is a significant influence of geographical latitude on the incidence of IBD [189,190] and CRC [191], with higher incidence in the north than in the south. Evidence from the majority of epidemiologic studies confirm a positive association between the concentration of serum 25(OH)D $_3$  and survival rate [192] and a negative association with the risk of colorectal neoplasms in patients with IBD, or sporadic CRC [193–195]. One

mechanism by which vitamin D affects IBD severity and prevents development of CAC is by regulating gut microbiota–host interactions through the synthesis of antimicrobial peptides [196].

In a randomized placebo-controlled trial, daily intake of 800 IU vitamin D $_3$  reduced serum levels of different inflammation markers (e.g., CRP, TNF $\alpha$ , IL6, IL8, IL1 $\beta$ , IL10), decreased the inflammation score by 77%, and was associated with lower risk of CRC [197]. Daily supplementation of healthy volunteers receiving the fat-rich Western-style diet with 0.5  $\mu$ g 1,25(OH) $_2$ D $_3$  upregulated in the rectal mucosa the expression of numerous genes involved in inflammation and immunity [198]. A systematic review found that high doses of vitamin D improved clinical and biochemical disease activity scores in vitamin D–deficient IBD patients [199]. In contrast, vitamin D $_3$  supplementation was not able to reduce the risk of recurrence in patients with resected colorectal adenomas, not even in patients with advanced adenocarcinoma having low serum 25(OH)D $_3$  levels [200].

The effect of vitamin D in animal models is much more consistent. Mice lacking either *Vdr* or *Cyp27b1* are highly susceptible to colitis and colitis-associated cancer [201]. In *Vdr* $^{-/-}$  mice, the tight junctions of intestinal epithelial cells are disrupted, wound healing mechanisms are impaired, and the intestinal transepithelial electric resistance is very low [202,203]. *Vdr* loss significantly increased tumorigenesis and activated EGFR and  $\beta$ -catenin signaling in chemically induced CAC [204]. The gut microbiome is changed in mice lacking *Vdr* in their intestine [205]. Reintroduction of *VDR* in the intestinal epithelial cells of *Vdr* $^{-/-}$  mice rescued them from colitis and death [206]. A study on *Cyp27b1* knockout mice demonstrated that 1,25(OH) $_2$ D $_3$  deficiency triggered growth and multiplicity of colon tumors, and generation of inflammatory cytokines that caused cellular senescence and DNA damage [207].

In experimental models, supplementation of vitamin D protected against inflammation and inflammation-associated cancer [156,208]. Vitamin D supplementation reduced dysplasia score in a dose-dependent manner in the azoxymethane (AOM)/dextran sulfate sodium (DSS)–induced colonic tumorigenesis model [209]. In a similar model, different vitamin D analogs reduced the number of colitis-associated tumors after 16 weeks [210].

#### 4.2.3 Vitamin D–dependent gene expression in inflammatory and cancer-promoting pathways in the intestines

In in vitro experiments, 1,25(OH) $_2$ D $_3$  inhibited most of the pathways (Wnt/ $\beta$ -catenin, NF- $\kappa$ B, PG pathway) responsible for the development of inflammation-associated cancer (Fig. 87.3) [10,211]. Treatment of established CRC cell lines with 1,25(OH) $_2$ D $_3$  inhibited the

expression of genes involved in proliferation and migration [212,213] and suppressed the Warburg effect [214].  $1,25(\text{OH})_2\text{D}_3$  also reversed cribriform morphology and adjusted spindle orientation—morphological characteristics of human colon cancer cells—by upregulating the expression of the tumor suppressor PTEN and stimulating CDC42 and PKC $\zeta$  [215].  $1,25(\text{OH})_2\text{D}_3$  induced expression of E-cadherin, GADD45, and EFTUD1 in both CRC cell lines and patient-derived colonic organoids [213]. It antagonized the Wnt/ $\beta$ -catenin pathway on multiple levels.  $1,25(\text{OH})_2\text{D}_3$  treatment prevented TCF/ $\beta$ -catenin-dependent transcription by binding of VDR to  $\beta$ -catenin, sequestered  $\beta$ -catenin to the tight junctions by supporting E-cadherin binding to  $\beta$ -catenin, and induced expression of the Wnt inhibitor DICKKOPF-1 [211].  $1,25(\text{OH})_2\text{D}_3$  blocked TGF $\beta$ 1/ $\beta$ 2-induced migration and invasion, upregulated E-cadherin expression, and inhibited the expression of N-cadherin, preventing the so called “cadherin switch” that plays an essential role in tumor invasiveness. Additionally, the level of MMP-2 and MMP-9 was decreased, inhibiting the invasion of the cancer cells into the circulatory system [216].  $1,25(\text{OH})_2\text{D}_3$  also prevented EMT, which is involved in the metastatic process [116,217].

In a bacteria-driven colitis model, high-dietary vitamin D—suppressed NF- $\kappa$ B activity and MAPK signaling in colonic epithelial cells. This led to reduced inflammatory cell infiltration and expression of proinflammatory cytokines in the cecum, and fewer invasive tumors in Smad3 $^{-/-}$  mice infected with *Helicobacter bilis* [108]. Vitamin D supplementation reduced tumor burden in the AOM/DSS model of CAC by inhibiting the transcriptional activity of NF- $\kappa$ B and p-38 MAPK [218]. The vitamin D analog Ro26-2198 significantly decreased expression of Cox-2, c-Myc, and pERK, thus delayed the onset of clinical colitis, and inhibited the development of dysplastic foci in an AOM/DSS model of CAC [219]. Vitamin D deficiency increased disease severity and mortality in the AOM/DSS colitis-associated cancer model [220]. Conversely, AOM/DSS treatment reduced serum  $25(\text{OH})\text{D}_3$  levels and intestinal VDR expression, at the same time increasing COX-2 levels. Challenging these mice with a vitamin D—deficient diet worsened the colitis score and increased mortality [221].

A further protective action of vitamin D against CAC is improving bacteria-induced impairment of the intestinal barrier function [222] and the upregulation of molecules important for maintaining intestinal integrity, such as claudins [109,208]. The intestinal vitamin D system supports mucosal barrier integrity by maintaining a healthy balance between proliferation and apoptosis of the epithelial cells [223]. An important factor that affects the antiinflammatory and antimitogenic effects of vitamin D in the colon is calcium intake [224,225].

Calcium supplementation and vitamin D status appear to act largely together, in an interdependent way [226,227]. Vitamin D supplementation for a year reduced COX-2/15-PGDH ratio in the normal rectal mucosa of patients with colorectal adenomas. The effect was even higher when vitamin D was given together with calcium [228].

Considering all these effects, vitamin D supplementation or less calcemic vitamin D analogs could be useful in ameliorating IBD and preventing inflammation-associated colorectal cancer. For additional information on the effect of vitamin D in IBD and CRC, see also Chapters 88 and 97.

#### 4.2.4 Effect of vitamin D in inflammation-associated prostate cancer

Prostate cancer (PCa) is the fourth most prevalent cancer in men worldwide, with an increasing incidence rate in most countries [229–232]. Inflammation is crucial in the etiology and development of PCa [233]. Chronic inflammation in noncancerous prostate correlated positively with development of PCa [234]. Areas of proliferative inflammatory atrophy (PIA) in the prostate are precursors of intraepithelial neoplasias (PIN) and carcinomas [139]. The source of inflammation is usually unknown. Exposure to infections, hormones, or dietary carcinogens could damage the prostate, leading to chronic inflammation and PIA. Even the normal prostate gland contains inflammatory cells, such as T and B lymphocytes, macrophages, and mast cells [139]. Both stromal and epithelial cells express immune-modulatory genes and contribute to the inflammatory environment. The stroma becomes reactive early in the PCa development and affects epithelial cell proliferation, differentiation, and apoptosis and mediates the immune response of epithelial cells during cancer progression [235,236]. Proinflammatory cytokines, released by T lymphocytes and macrophages, induce COX-2 expression in adjacent tumor cells and stimulate angiogenesis in stromal tissues [237]. Interestingly, however, a prospective cohort study found that the presence of chronic inflammation in the prostate tumor was associated with better prognosis for the patients [238].

The vitamin D system is often deregulated in PCa, impairing the cancer preventive action of vitamin D [31]. High expression of VDR in the tumor tissue was associated with reduced risk of lethal PCa [239]. CYP27B1 expression is reduced in prostate tumors [240] due to promoter hypermethylation [241], or repression by the transcription factor growth factor independence-1 [242]. Higher levels of vitamin D metabolizing enzymes were detected both in the benign and cancerous prostate epithelia compared with the surrounding stroma [243]. Two VDR SNPs were associated with prostate cancer risk, independent of the age

of the participant or the aggressiveness of the tumor [244].

The epidemiologic evidence regarding the antiinflammatory and cancer preventive effect of vitamin D in prostate diseases is mixed. Low 25(OH) $D_3$  serum levels were associated with inflammation, increased odds of adverse pathology, aggressive tumors, and higher mortality [32,245–247]. Association with overall risk is less convincing [248,249]. There are even studies that found a U-shaped effect [250]. In Finland, the highest risk for developing prostate cancer was for men in the highest tertile of 25(OH) $D_3$  level, whereas mortality was highest in the lowest 25(OH) $D_3$  tertile [251]. Other studies found that high serum levels of 25(OH) $D_3$  correlated with better survival in all stages and grades of PCa [30,252] and that posttreatment 1,25(OH) $_2D_3$  levels in patients with aggressive tumors inversely correlated with all-cause and PCa-specific mortality [253]. More-and-more evidence is pointing toward racial disparities in the incidence and mortality from PCa [254–256]. Whether the fact that African Americans have a higher incidence rate of PCa than Caucasians is due mainly to socioeconomic factors, or also due to the lower vitamin D levels prevalent in this population, is not yet clear [257].

Vitamin D supplementation reduced inflammation and tumor size in PCa patients by upregulating growth differentiation factor-15, an antiinflammatory molecule markedly reduced in PCa [258]. In a pilot study, supplementation of 2,000 IU of vitamin D per day for 21 months increased prostate-specific antigen (PSA) doubling time in PCa patients [259]. Combining 1,25(OH) $_2D_3$  with the nonsteroidal antiinflammatory drug naproxen prolonged PSA doubling time compared with baseline in more than 75% of patients with early recurrent PCa [260].

Several mouse models have demonstrated the cancer preventive effect of vitamin D. A high vitamin D diet (5,000 IU/kg) or 1,25(OH) $_2D_3$  administration significantly inhibited growth of PC3 cell xenografts in mice [261]. In the TgAPT $_{121}$  mouse model for early steps of prostate carcinogenesis, disruption of the vitamin D signaling accelerated the development of tumors from high-grade PIN, while high-dietary vitamin D intake reduced tumor incidence [262]. A diet low in vitamin D (25 IU VD/kg diet), or *Vdr* deletion, supported procarcinogenic transformation that accelerated PCa development [263]. In a mouse model of PCa that recapitulates the various steps of tumor development from the prostatic intraepithelial neoplastic lesions to adenocarcinoma, 1,25(OH) $_2D_3$  inhibited progression from low-grade PIN to high-grade PIN if administered before neoplastic transformation [264]. In the TRAMP model of PCa, administration of vitamin D during early stages initially prevented the development of aggressive PCa, but a prolonged administration seemed to increase the

aggressiveness of the metastatic process [265]. Lack of *Vdr* accelerated tumor progression in the LPB-Tag model of PCa as well [266]. The expression of the vitamin D metabolizing enzymes in the prostate of rats changes during aging: *Cyp27b1* expression decreased with age, mainly in areas with hyperplasia, premalignant lesions, and tumors, while expression of *Cyp24a1* increased in both the normal and transformed prostate [267].

#### **4.2.5 Vitamin D–dependent gene expression in inflammatory and cancer-promoting pathways in the prostate**

Vitamin D regulates not only the epithelial cells but also different other cell types, such as immune cells or stromal cells, and modulates the complex interactions among them. In prostate epithelial cells, 1,25(OH) $_2D_3$  treatment modulated a complex network of pathways that would slow or restrain tumorigenesis. An integrative network-based analysis of publicly available mRNA and microRNA datasets showed that in the LNCaP prostate cancer cells, 1,25(OH) $_2D_3$  treatment affected 15 signaling pathways, mostly inhibiting cell cycle–related and cancer-specific processes [268]. In the normal prostate cell line RWPE1, 1,25(OH) $_2D_3$  treatment inhibited pathways regulating proliferation, angiogenesis, and induced proapoptotic ones. The major inflammatory pathways, COX-2/PGE $_2$ , and NF- $\kappa$ B, are also active in PCa and often correlate with lower vitamin D levels [32]. 1,25(OH) $_2D_3$  suppressed Wnt/ $\beta$ -catenin, NF- $\kappa$ B, Notch signaling, inhibited the JAK-STAT3 inflammatory pathway reducing the expression of the proinflammatory cytokines IL1, IL17, IL8, and IL6 [269], and suppressed early prostate carcinogenesis [262]. In normal human prostate cells and in primary tumor-derived cancer cells, 1,25(OH) $_2D_3$  induced MKP5 expression in a VDR-dependent manner and suppressed TNF $\alpha$  signaling. This led to inhibition of p38 activity and IL6 synthesis, blocking the procarcinogenic inflammatory processes [270]. 1,25(OH) $_2D_3$  inhibited NF- $\kappa$ B signaling by preventing nuclear translocation of the NF- $\kappa$ B subunit p65. The Rel-B subunit is overexpressed in androgen-independent tumors with high Gleason scores, conferring radiation resistance. 1,25(OH) $_2D_3$  suppressed radiation-mediated activation of the Rel-B subunit, enhancing sensitivity of androgen-dependent PCa cells to ionizing radiation [271].

Several studies suggest a central role for COX-2 in prostate tumorigenesis [54]. It was even suggested that COX-2 expression is an independent predictor for PCa recurrence [272]. 1,25(OH) $_2D_3$  inhibited the COX-2/PGE $_2$  pathway both in established PCa cell lines and in primary PCa cells. It reduced expression of COX-2 and of PG receptors, and induced 15-PGDH levels,

inhibiting PGE<sub>2</sub>-mediated proliferative, proangiogenic, and antiapoptotic signaling [54,273]. Another way by which VDR-bound 1,25(OH)<sub>2</sub>D regulates antiinflammatory and antitumorigenic pathways in the prostate is by regulating the expression of DICER1 and several microRNAs, such as miR-126-3p, miR 154-5p, and miR-21-5p [274].

Dietary supplementation with 1,25(OH)<sub>2</sub>D<sub>3</sub> and soy inhibited the growth of PCa xenografts in a mouse model. It increased expression of antiproliferative (p21, IGFBP-3) and proapoptotic (Bax) genes, inhibited antiapoptotic (Bcl-2) genes, and suppressed the PG pathway (COX-2, 15-PGDH, PG receptors) [275]. Vitamin D supplementation was able to prevent high-calcium diet-induced progression of PIN, by inhibiting the upregulation of the expression of the cationic channel TRPC6, and the calcium-sensing receptor (CaSR) [276].

Understanding the mechanism of action of vitamin D in PCa could lead to new strategies in using vitamin D for the benefit of PCa patients. Both preclinical and clinical studies showed that vitamin D potentiates the action of different drugs that have antitumor effect in PCa [277,278]. For additional information, see also Chapter 91.

#### **4.2.6 Effect of vitamin D in inflammation-associated breast cancer**

Breast cancer (BCa) is one of the most frequent cancers and the main cause of cancer-related deaths in women [279]. It is a very heterogeneous disease. The etiology is not completely understood; therefore, it is not clear how much impact has inflammation in breast tumorigenesis [280]. Evidence is mounting though that innate and adaptive leukocytes play an important role in breast carcinogenesis, as human BCa development is paralleled by abundant infiltration of immune cells [281]. Activated B cells were found in tumor-associated stroma, mainly in early breast tumors, while infiltrating T lymphocytes are more abundant in higher-grade ductal carcinomas in situ (DCIS) and in invasive carcinomas. The percentage of regulatory T cells in the tumor and surrounding stroma increases in parallel with disease stage and promotes immunosuppression and tumor progression [281].

The COX-2/PGE<sub>2</sub> pathway seems to promote Treg differentiation [282]. An active IL6/JAK/STAT3 signaling is important for the invasiveness and metastatic potential of breast tumor cells [283]. The cytokine IL1 plays a central role in the intercellular and intracellular cross-talk in the microenvironment of breast tumors [284]. Vitamin D is able to inhibit all these pathways. Breast epithelial cells express the vitamin D system and have the capacity to synthesize the active vitamin

D metabolite 1,25(OH)<sub>2</sub>D<sub>3</sub>. Vitamin D signaling and metabolism becomes deregulated during BCa progression [285]. Both VDR expression and 1,25(OH)<sub>2</sub>D<sub>3</sub> action alter with the transformation process [111]. The VDR is expressed in normal breast tissue; in benign and malignant tumors, however, its levels decrease with invasiveness of the tumor. VDR levels correlated with estrogen receptor (ER) $\alpha$  in breast carcinomas. CYP27B1 expression decreased during malignant progression, while CYP24A1 expression increased [286].

The findings of epidemiological studies regarding the effect of vitamin D intake and 25(OH)D<sub>3</sub> serum levels on risk, progression, aggressiveness, and survival/mortality of BCa are mixed. Randomized controlled trials observed only slight benefits of vitamin D supplementation on BCa development [111,287]. A metaanalysis found that concentrations higher than 50 ng/mL 25(OH)D<sub>3</sub> in the serum were associated with 50% lower risk of developing BCa [288,289], while other studies found no inverse association [290]. A randomized placebo-controlled trial detected no correlation between low (400 IU) daily doses of vitamin D<sub>3</sub> and BCa risk in postmenopausal women [291,292]. Higher vitamin D<sub>3</sub> intake (1100 IU/day), which raised 25(OH)D<sub>3</sub> serum concentrations up to more than 80 nmol/L, had a preventive effect in many types of cancers including BCa [152]. While a metaanalysis with data from 17 prospective study cohorts found no association between serum 25(OH)D<sub>3</sub> levels and BCa risk [293], a metaanalysis on BCa survival confirmed that serum 25(OH)D<sub>3</sub> concentrations have a strong dose-dependent inverse correlation with BCa mortality [294]. Prediagnostic 25(OH)D<sub>3</sub> levels modulated the expression of gene sets involved in proliferation, migration, and inflammation and were inversely associated with recurrence risk in patients with ER-positive tumors [295].

#### **4.2.7 Vitamin D-dependent gene expression in inflammatory and cancer-promoting pathways in the breast**

The COX-2/PGE<sub>2</sub> pathway is activated also in BCa, in both epithelial cells, lymphocytes, and tumor infiltrating macrophages [296]. PGE<sub>2</sub> induces aromatase expression, leading to higher estrogen (E<sub>2</sub>) levels in BCa cells, increasing proliferation, angiogenesis, and invasion [297]. Aromatase, an enzyme involved in estrogen synthesis, is overexpressed in BCa. In normal tissue, aromatase expression is driven by the glucocorticoid-stimulated promoter I.4 in the CYP19 gene, while in BCa, it is stimulated through the tumor-specific proximal promoter I.3 and II, in a cAMP-mediated way [298]. There is a strong correlation between aromatase activity and COX-2 expression in breast tumors as

PGE<sub>2</sub> is considered the most potent natural inducer of this promoter region. COX-2 inhibitors suppress also aromatase activity [299]. In BCa patients, COX-2 levels were higher than in normal breast tissue and were associated with low VDR expression and low serum 25(OH)D<sub>3</sub> levels [300]. In BCa cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> suppressed COX-2 and stimulated 15-PGDH expression leading to lower PG levels [166,301,302]. Treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> and the COX-2 inhibitor celecoxib inhibited expression of COX-2 in a cooperative way [303]. 15-PGDH is considered a tumor suppressor also in BCa [304], similarly as in CAC.

1,25(OH)<sub>2</sub>D<sub>3</sub> influences the activity of aromatase in a tissue-dependent manner. In BCa cells, it inhibited aromatase activity and reduced estrogen synthesis. 1,25(OH)<sub>2</sub>D<sub>3</sub> injections in mice with MCF-7 xenografts confirmed these *in vitro* results, by inhibiting the expression of aromatase in the newly developed tumors and the surrounding mammary adipose tissue. However, in osteosarcoma cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> had the opposite effect, inducing aromatase expression. This tissue-specific regulation makes 1,25(OH)<sub>2</sub>D<sub>3</sub> a selective aromatase modulator that can inhibit breast carcinogenesis, while protecting bone mineralization [301].

High-dietary intake of vitamin D and injected 1,25(OH)<sub>2</sub>D<sub>3</sub> had comparable tumor-reducing effects (50%–60%) in mice carrying MCF-7 xenografts. Both methods of vitamin D supplementation inhibited expression of aromatase, ER $\alpha$ , and the COX-2 pathway genes and reduced the level of estrone and estradiol. Vitamin D and 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited proliferation by increasing p21 and IGFBP-3 gene expression and induced apoptosis of the BCa xenografts by upregulating the proapoptotic Bax and downregulating the antiapoptotic Bcl-2 [261].

*In vitro*, 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analog BXL0124 prevented growth of BCa stem cell subpopulations shown to be responsible for BCa initiation [305]. Overexpression of VDR in CD133<sup>+</sup> cancer stem cells and treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> sensitized these to tamoxifen and inhibited spheroid formation by inhibiting Wnt/ $\beta$ -catenin signaling [306]. BXL0124 prevented the invasive capacity of cancer cells by inhibiting the expression of the stem cell marker CD44 that further repressed STAT3 signaling, which is responsible for BCa progression [307]. In MCF-7 BCa cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment inhibited nuclear translocation of the p65 subunit of the NF- $\kappa$ B, inhibiting this proinflammatory pathway [308]. In MCF12F normal breast cells, 25(OH)D<sub>3</sub> protected against cellular stress, oxidative stress, hypoxia, and apoptosis [309]. In mammary glands resected from mice and treated with carcinogens to induce precancerous lesions, treatment with 25(OH)D<sub>3</sub> had a

chemopreventive effect [310]. In the ER-negative BCa cell line MDA-MB-453, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited the Ras/MEK/ERK signaling pathway [311]. For additional information, see also Chapter 88.

#### 4.2.8 Effect of vitamin D in inflammation-associated pancreatic cancer

Pancreatic cancer is an aggressive disease with high recurrence and low survival rate; it is the fourth leading cause of cancer-related deaths. Pancreatitis, the chronic inflammation of the pancreas, is a main risk factor for pancreatic ductal adenocarcinoma (PDAC). Pancreatic tumors have inflammatory elements, and cancer-associated fibroblasts are infiltrating the tumor stroma. The pancreatic stellate cells (PSCs) are quiescent fibroblast-like cells that become activated due to injury or inflammation and acquire tumor supportive features [312]. Genomic investigations revealed 12 essential overlapping molecular signaling pathways altered in this type of cancer [313]. The key molecules (KRAS, MAPK, EGFR, STAT, CCK-BR, VEGF, PDGFR, TGF- $\beta$ , SMAD4, MMPs, COX-2) involved in pancreatic tumorigenesis affect tumor development and progression and invasion, inhibition of apoptosis, metastasis, and angiogenesis [314]. The Wnt/ $\beta$ -catenin pathway is required for initiation of pancreatic carcinogenesis [315]. The known pathways linking inflammation and cancer, NF- $\kappa$ B, COX-2, STAT3, and Wnt/ $\beta$ -catenin, are activated also in pancreatic tumors [316–318].

The different cell types of the pancreas express the vitamin D system at different levels. In pancreatic cancer, however, this system becomes altered. The VDR is highly expressed in the endocrine islets but is barely detectable in the exocrine pancreas both in patients with chronic pancreatitis and in patients with PDAC [319]. The VDR is expressed also in the stroma of pancreatic tumors. In chronic pancreatitis patients, the expression of the degrading enzyme CYP24A1 was highest in the islets, and in adenocarcinomas, the tumor cells expressed more CYP24A1 than any other cell type. During PDAC development, the islets lose CYP24A1, while the transformed ductal cells upregulate CYP24A1 expression, impairing the antiproliferative effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> in these cells [319,320]. Moreover, silencing CYP24A1 inhibited proliferation and invasion of PDAC cells without affecting their migrating ability [320]. In a Canadian population, SNPs in CYP24A1, CYP2R1, vitamin D-binding protein, retinoid X receptor alpha, and megalin were significantly associated with the risk of developing pancreatic cancer [321]. The pancreata of *Vdr*<sup>−/−</sup> mice have periacinar and periductal fibrosis, demonstrating the importance of an intact vitamin D system for normal pancreatic function [312].

The correlation between vitamin D and pancreatic cancer has been controversial, and its putative beneficial role was not confirmed by all studies [322–326]. A meta-analysis found that pancreatic cancer patients with high blood 25(OH)D<sub>3</sub> levels had significantly improved survival, but no association was seen between 25(OH)D<sub>3</sub> levels and cancer risk [327]. Ecological studies found an inverse relationship between UVB radiation and pancreatic cancer risk [328]. Inflammatory biomarkers were increased in PDAC patients with vitamin D deficiency, independent of disease stage [329]. A nested case–control study in a cohort of men from Finland observed an unexpected association between high pre-diagnostic serum 25(OH)D<sub>3</sub> levels and a threefold increased pancreatic cancer risk [330]. These results could not be entirely confirmed in a cohort of male and female subjects from the United States, where high concentrations of serum 25(OH)D<sub>3</sub> were not associated with a higher risk of pancreatic cancer. In the Prostate, Lung, Ovarian, and Colorectal Cancer Screening Trial cohort, increasing serum 25(OH)D<sub>3</sub> levels associated positively with the risk of pancreatic cancer, but only in men with low sun exposure, or men with blood collected during fall or winter [331].

Studies on dietary vitamin D intake and pancreatic cancer are also inconclusive. Supplementation with 600 IU/day vitamin D was associated with lower risk of pancreatic cancer in a prospective study [332]; on the other hand, a pooled analysis of 14 cohorts found no association between vitamin D intake and pancreatic cancer [333]. A phase II trial with seocalcitol (EB1089), a vitamin D analog that inhibited growth of pancreatic cancer xenografts in vivo, found no antitumorigenic effects in patients with inoperable pancreatic cancer [334]. However, these patients had very advanced disease, and the level of VDR in the tumor was unknown. In another phase II trial, high-dose (0.5 µg/kg) calcitriol in combination with docetaxel moderately increased the time-to-progression in patients with incurable pancreatic cancer [335].

In the Ela1-TAg transgenic mouse model of pancreatic acinar cell carcinoma, vitamin D supplementation had no detectable effect on tumor development [336]. In contrast, in mouse models of acute and chronic pancreatitis, therapy with calcipotriol (a potent and non-hypercalcemic vitamin D analog) reduced fibrosis and inflammation [312]. In an orthotopic allograft PDCA model using immune-competent hosts, calcipotriol administration improved the efficacy of gemcitabine treatment, reducing tumor volume, tumor growth, and prolonged survival, compared with the gemcitabine treatment alone [312].

In several pancreatic cancer cell lines, VDR was essential for the survival of rapidly dividing cells, and depletion of VDR increased the sensitivity of the cancer cells

to gemcitabine treatment, suggesting that inhibition of VDR might provide a new way to enhance the efficacy of genotoxic drugs [337].

#### **4.2.9 Vitamin D–dependent gene expression in inflammatory and cancer-promoting pathways in the pancreas**

Very often the cytokines secreted by the stroma and the activated pancreatic stellate cells play an essential role in promoting cancer initiation in the pancreas [338]. Liganded VDR can ameliorate this process, reducing markers of inflammation and fibrosis [312]. In activated PSCs isolated from mouse models of acute and chronic pancreatitis, calcipotriol inhibited expression of cancer-signature genes, such as inflammatory cytokines and growth factors, such as WNT2B, WNT2A, IL6, and CCL2, through a cross-talk with the TGF-β/sonic hedgehog pathway [312]. In a coculture model of the pancreatic epithelial cell line (MIAPaCa-2) with activated human cancer-associated PSCs, activation of the stromal, but not epithelial, VDR inhibited expression of genes involved in proliferation, survival, epithelial-to-mesenchymal transition, and chemoresistance. Additionally, calcipotriol inhibited phosphorylation of STAT3 [312].

In in vitro and in vivo studies, both in pancreatic tissue and in xenografts, different 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs inhibited proliferation, migration, and invasion, and induced apoptosis, mainly by inhibiting the Akt pathway [339]. 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analog 19-nor-1α,25-(OH)<sub>2</sub>D<sub>2</sub> (paricalcitol) induced cell cycle arrest in G0/G1 phase and consequently inhibited proliferation of pancreatic tumor cells by upregulating the expression of p21 and p27 [340,341].

In pancreatic cancer cells, Arensman et al. identified a bidirectional feedback loop between vitamin D and Wnt signaling [342]. Activation of the Wnt pathway induced VDR expression, leading to significantly higher VDR levels in pancreatic cancer cell lines with high autocrine Wnt activity, compared with cells with low Wnt activity. Calcipotriol inhibited Wnt/β-catenin activity in the cells with high Wnt activity, by reducing the protein level of the Wnt coreceptor LRP6 [342]. The mechanism involves the direct transcriptional upregulation of the low-density lipoprotein receptor adaptor protein 1 (LDLRAP1). LDLRAP1 is required for endocytosis of LDL receptors and probably facilitates the internalization of LRP6 and its degradation through endosomal trafficking to lysosomes [342].

As vitamin D affects both the tumor and the stroma, it could support coupling stromal reprogramming with tumor-directed cytotoxic and immunologic drugs in innovative PDCA therapies. For more information, see also [Chapter 92](#).

#### 4.2.10 Effect of vitamin D in inflammation-associated hepatocellular cancer

Chronic liver disease and cirrhosis are a major global health concern. Hepatocellular carcinoma (HCC) has a complex molecular signature with two major determinants. Its etiology can be associated either with cirrhosis due to hepatitis infection, alcohol abuse, mutagenic agents, or metabolic disruptions or with different mutations in tumor suppressor genes or oncogenes (e.g., *p53*, *MYC*, *TGF- $\beta$* , *PTEN*, *EGFR*) that alter key carcinogenic signaling pathways (*VEGF*, *PDGF*, *EGF*, *IGF*, *HGF/c-MET*, *MAPK*, *mTOR*, *Wnt/ $\beta$ -catenin*) [343–345].

Low serum 25(OH) $D_3$  levels inversely correlated with the degree of liver dysfunction [346]. Vitamin D deficiency was linked also to inflammatory and metabolic liver diseases, including infection with hepatitis B and C virus (HBV/HCV) [347]. Severe vitamin D deficiency is common in patients with chronic hepatitis C (CHC). Higher 25(OH) $D_3$  levels were associated with less inflammation and less liver fibrosis in CHC patients [348]. Some of the effects of vitamin D are mediated by microRNAs that have proven to be VDR targets, such as miR-27, miR-125, and miR-155 [349,350]. In vitro 1,25(OH) $_2D_3$  treatment upregulated miR-375 and inhibited genes involved in EMT, such as YAP-1 and c-MYC [351]. In an Egyptian hepatitis C virus (HCV)–infected patient group, low vitamin D levels, serum IL13, and miR-135a correlated with unresponsiveness to antiviral treatment and high HCC risk [352].

Fibrosis, a progressive deposition of extracellular matrix components, is a typical signature of hepatic cirrhosis and involves activation of hepatic stellate cells (HSCs). VDR is expressed in HSCs, where it regulates hepatic fibrogenesis by preventing activation of profibrotic genes [353–355]. Activated HSCs provide a strong tumor-promoting microenvironment in hepatic cancer development. Similar to its effects in PSC, the vitamin D analog calcipotriol induces accumulation of lipid droplets in HSC, a sign of quiescence of stellate cells [356]. Paricalcitol, an 1,25(OH) $_2D_3$  analog, reduced inflammatory liver damage and ameliorated fibrosis in vivo [357]. In HSCs, the signaling adapter and autophagy substrate p62 is critical for the proper activity of VDR, namely for its heterodimerization with RXR. In hyperactivated HSCs, 1,25(OH) $_2D_3$  was unable to prevent fibrosis, probably due to the very low levels of p62, leading to reduced binding of liganded VDR to its target genes [356].

The high expression of CYP2R1 in liver cells from patients with chronic hepatitis C was associated with a high expression of VDR in infiltrated inflammatory cells and low portal inflammation, suggesting that vitamin D may control the inflammatory response in patients with this disease [358]. A SNP involved in the development of

many endocrine autoimmune diseases, the CYP27B1-1260 promoter polymorphism (rs10877012), was associated with sustained virological response rates in Caucasian patients with HCV genotypes 1, 2, and 3, receiving interferon- $\alpha$ -based treatment. Genotype AA of rs10877012 correlated with higher serum 1,25(OH) $_2D_3$  levels, compared with the AC or CC genotypes. Genotype CC was more common in the patients with HCV genotype 1 than in the healthy participants [359]. Further polymorphisms in CYP27B1 and CYP24A1 were associated with higher risk to develop nonalcoholic fatty liver disease (NAFLD) in China [360]. Indeed, NAFLD has been associated with vitamin D deficiency. Vitamin D status influences the severity of NAFLD by regulating not only the intestinal innate immunity but also the composition of the intestinal microbiota [361]. In an animal model of nonalcoholic steatohepatitis (NASH), an advanced form of NAFLD, vitamin D deficiency exacerbated the severity of the disease [362]. In patients with NASH, VDR levels were negatively associated with the activity score of NAFLD, supporting the involvement of VDR in the regulation of the inflammatory processes that develop during this disease [358].

The molecular actions of 1,25(OH) $_2D_3$  in hepatocellular carcinoma are less well understood [344]. 1,25(OH) $_2D_3$  treatment of HCC cell lines inhibited cell growth and induced expression of the cell cycle inhibitor p21. In parallel, 1,25(OH) $_2D_3$  decreased the expression of histone deacetylase 2, an enzyme usually overexpressed in HCC tumors, leading to inhibition of transcription of p21 [345]. In rats, high-dietary vitamin D intake reduced the level of the inflammatory markers IL1 $\beta$  and TNF $\alpha$  [363]. In a liver fibrosis model, calcipotriol reduced fibrosis and inhibited activation of HSCs by affecting the NF- $\kappa$ B pathway [354]. In a mouse model of HCC, 1,25(OH) $_2D_3$  treatment reduced tumorigenesis by inhibiting inflammatory cytokine secretion [364], while in the Smad3-deficient mice, it modulated signaling through TLR7 and the Wnt pathway [365]. A vitamin D $_2$  analog, doxercalciferol, given together with carnosic acid, increased HCC cell death through autophagy and apoptosis [366].

## 5. Conclusions

Vitamin D deficiency is prevalent, and the vitamin D system is compromised in many inflammatory conditions and cancers. It is not yet completely and convincingly demonstrated whether inadequate vitamin D level is a risk factor or a consequence of these diseases. As vitamin D deficiency should be avoided in any event, we need consensus what the adequate serum vitamin D levels should be and how to reach these levels, keeping

the potential effects on cancer risk and inflammation in mind.

Regardless of its extrinsic or intrinsic origin, cancer-related inflammation is a crucial process in tumorigenesis. It supports proliferation and survival of tumor cells, angiogenesis, migration, invasion, and metastasis; suppresses the adaptive immunity; and inhibits the response to treatment. Vitamin D is able to counteract most of these carcinogenic processes by complex, cell- and tissue-dependent molecular mechanisms, where  $1,25(\text{OH})_2\text{D}_3$  or synthetic vitamin D analogs activate gene expression and different signaling pathways in both VDR-dependent and independent manner. Although the preclinical studies support the antiinflammatory and antitumorigenic effects of vitamin D and of the vitamin D system, clinical trials have yielded controversial results on the influence of vitamin D and of its analogs on the prevalence and survival rate in patients with different types of (inflammation-associated) cancers. Whether this could be attributed, at least in part, to the tolerogenic effects of vitamin D, should be examined in more detail.

The antineoplastic action of vitamin D and its natural or synthetic analogs relies on induction of differentiation and apoptosis, inhibition of proliferation, invasiveness, and angiogenesis. These antitumorigenic effects might be weakened by the immunotolerogenic effects of  $1,25(\text{OH})_2\text{D}_3$  such as inhibition of effector T cells and upregulation of regulatory T cells [367]. Cancer immunotherapy needs a functional immune system, e.g., enhanced T cell immunity at the tumor site, to be effective. Therefore, the immunomodulatory properties of vitamin D and its analogs should be considered when designing clinical trials using these agents in treatment of cancer patients. Thus, there is vital need for new, more effective and selective  $1,25(\text{OH})_2\text{D}_3$  analogs that should be tested in faultlessly designed clinical trials.

## 6. Summary points

- Both the innate and adaptive immune system express VDR and the vitamin D–metabolizing enzymes almost ubiquitously.
- Inflammation affects  $1,25(\text{OH})_2\text{D}_3$  levels by regulating the expression level of the metabolizing enzymes CYP27B1 and CYP24A1, and of the VDR.
- Vitamin D ameliorates severity of chronic inflammations by regulating the innate and adaptive immune system.
- Vitamin D affects most hallmarks of cancer and prevents inflammation-associated cancers by regulating events downstream both the extrinsic and intrinsic inflammatory pathways.

# Vitamin D actions in mammary gland and breast cancer

JoEllen Welsh<sup>1</sup> and Min Ji Bak<sup>2</sup>

<sup>1</sup>Department of Environmental Health Sciences, University at Albany Cancer Research Center, Albany, NY, United States

<sup>2</sup>University at Albany Cancer Research Center, Albany, NY, United States

## OBJECTIVES

- Present an overview of breast cancer biology as a framework for evaluating the role of the vitamin D pathway in the prevention and treatment.
- Review observational and interventional studies designed to address the impact of vitamin D on human breast cancer.
- Discuss the expression and function of the vitamin D pathway in breast cancer model systems.
- Highlight mechanisms by which vitamin D and its nuclear receptor modulate breast cancer.

## 1. Introduction

### 1.1 Overview of breast cancer

According to the Center for Disease Control's 2019 statistics [1], breast cancer is the most commonly diagnosed malignancy in US women with over 264,000 cases annually. The majority of women diagnosed already harbor invasive cancers with a high risk for the development of deadly metastases. Like many of the solid tumors common in populations living in industrialized countries, the incidence and mortality of breast cancer increase with age. In fact, 80% of diagnoses and almost 90% of deaths from breast cancer are in women over the age of 50. Between 1999 and 2019, the age-adjusted breast cancer mortality rate per 100,000 women has

declined from 26.6 to 19.4, an encouraging trend which has been attributed to enhanced screening, new treatment approaches, and prevention strategies. Despite these improvements, breast cancer kills over 42,000 women yearly in the US. Breast cancer is increasingly recognized as a global health problem, as data from the World Health Organization's Global Cancer Observatory indicate that breast cancer is the most prevalent cancer worldwide (with over 2.2 million cases diagnosed and over 680,000 deaths in 2020).

Risk factors and etiologic agents associated with breast cancer include those related to reproductive history (age at menarche, age at menopause, nulliparity, parity after age 30, hormone replacement therapy), genetics, radiation exposure, obesity, and diet. Vitamin D is one dietary factor that has been mechanistically linked to breast cancer etiology and is the focus of this chapter. Established tumor suppressor genes associated with familial breast cancer include the breast cancer susceptibility genes *BRCA1* and *BRCA2*, *p53*, and *ATM*; however, it is estimated that less than 10% of breast cancers can be attributed to inherited loss of function mutations in these genes. The vast majority of breast cancer cases are sporadic in nature although, as described below, several characteristic molecular changes have been linked with disease pathology and prognosis.

### 1.2 Subtypes of breast cancer and prognosis

Breast cancer collectively refers to several neoplastic diseases that arise in the mammary gland. Of the multiple cell types in the gland (epithelial cells, stromal fibroblasts, adipocytes, immune cells), it is the epithelial cells

that give rise to the common clinically relevant breast cancers. Within the mammary epithelium, carcinomas can originate from either the luminal cells or the basal cells of the ducts and lobules [2]. Ductal carcinoma is the most commonly diagnosed type, accounting for approximately 85% of all breast cancers. The development of invasive cancer from precursor lesions such as ductal carcinoma in situ (DCIS) is driven by genetic and epi-genetic changes within the epithelial cells and altered signaling between the epithelial cells and their microenvironment. The resulting carcinomas are highly heterogeneous and distinct subtypes have been identified based on histopathology and genomic profiling. Tumors that express the estrogen receptor alpha (ER, encoded by the *ESR* gene) and the progesterone receptor (PR, encoded by the *PGR* gene) account for 60%–70% of the breast cancer cases diagnosed in humans [3]. While less common, tumors lacking ER or PR and those with high expression of the growth factor receptor, HER2 (encoded by the *ERBB2* gene), are generally more aggressive with reduced survival rates.

Despite continued research, breast cancer is associated with a 20% mortality rate within the first 5 years after diagnosis. The severity of the disease reflects many factors including metastatic potential, hormone independence, drug resistance, and histological heterogeneity. Sites of breast cancer metastasis include regional lymph nodes, lung, liver, brain, and bone. The median survival of patients with distant metastases is 2–3 years. Development of bone metastases is particularly common with approximately 80% of patients with metastatic disease exhibiting skeletal involvement. Mechanisms underlying the establishment and progression of breast tumor growth in bone are poorly understood, although high rates of bone turnover appear to favor skeletal metastases.

Treatment of breast cancer is based on histopathological features such as grade, stage, and hormone/growth factor receptor status as evaluated at diagnosis. Lesions confined to the duct which are termed DCIS are routinely treated by surgical removal (lumpectomy or mastectomy) followed by radiation therapy and in some cases antiestrogen therapies. For invasive breast cancers, surgery is followed by systemic therapy which will vary based on tumor stage and molecular characteristics. Patients with ER+ and/or PR+ tumors typically receive hormone ablation therapies such as the antiestrogen tamoxifen or inhibitors of CYP19, the aromatase enzyme that drives the local synthesis of estrogen in the breast. For those women whose tumors overexpress the growth factor receptor HER2, targeted therapy with antibodies such as Herceptin (Trastuzumab) is standard, usually in combination with

chemotherapy. Patients whose tumors lack hormone and growth factor receptors, which are called triple-negative breast cancers (TNBC) are candidates for systemic chemotherapeutic regimens. Additional treatments that target cell cycle, DNA repair, and immune checkpoints may be employed for those with advanced disease or drug resistance. Newly identified molecular features and the presence of distinct oncogenic pathways are continuously emerging as significant therapeutic targets for all subtypes of breast cancer. As discussed in detail below, the presence of the VDR in the majority of breast tumors suggests it may represent a molecular target for therapy.

### 1.3 Molecular heterogeneity of human breast cancer

Within the last decade, intensive genomic profiling of human tumors has enabled detailed molecular characterization of breast cancers, leading to the identification of five major subtypes of invasive ductal carcinoma [4–8]. These five subtypes, which represent about 80% of all breast cancers, include Luminal A, Luminal B, Basal, HER2 positive, and Normal Breast-like [4]. Each subtype exhibits distinct profiles of hormone and growth factor receptors (ER, PR, HER2), cytokeratins, and proliferation markers. Most importantly, each tumor subtype has a characteristic prognostic outcome, with Luminal A tumors (which are ER+, PR+, and HER2– and usually express functional p53 protein) typically having a much better prognosis than the other types. Luminal B tumors tend to be ER+, PR+, and HER2+ and are usually of higher grade with more frequent *TP53* mutations than Luminal A tumors. The HER2 subtype, with a characteristic elevation of HER2 growth factor receptor signaling (usually due to genomic amplification), is negative for ER and PR and usually of high tumor grade. Basal tumors are predominantly ER–, PR–, and HER2– (and therefore usually classified as TNBC) and often express HER1 and/or cytokeratin 5/6 proteins and *TP53* mutations. Most breast cancers that develop in women with loss of function mutations in BRCA1 cluster with the basal molecular subtype whereas BRCA2 mutated tumors are more likely to be ER+ [9]. Although many trials have assessed the impact of nutrients, including vitamin D, on breast cancer risk and progression, few have been designed to stratify results by molecular subtype. This review will highlight the cumulative data on vitamin D actions in breast cancer while emphasizing the gaps in knowledge regarding its effects on specific molecular subtypes.

### 1.4 VDR, mammary cell lineages, and breast cancer cells of origin

The mammary gland contains multiple stem, progenitor, and differentiated cell types that maintain tissue homeostasis and function throughout the dynamic changes associated with puberty, pregnancy, lactation, and involution [10]. It has been suggested that the molecular heterogeneity of breast tumors might reflect distinct cells of origin [11]. That is, the initial target for transformation could be a mammary stem cell, a committed progenitor cell, or a differentiated luminal or basal epithelial cell, all of which would give rise to tumors with distinct features. Santagata et al. [12] mapped nuclear receptor expression during mammary gland lineage determination and reported that VDR was not expressed in early progenitor cells or differentiated basal cells, but was acquired in a subset of mature luminal cell types. Thus, the expression and function of the vitamin D pathway in a particular tumor will likely depend on its cell of origin [13].

A related issue is a recognition that human breast cancers contain “cancer stem cells” or “tumor initiating cells” that drive tumor initiation and/or progression. Advances in techniques to identify and isolate mammary stem cells support the concept that stem cell populations exist in human breast tumors and that analogous populations can be identified in certain murine tumors and human xenografts. Because stem cells theoretically give rise to the entire heterogeneous tumor cell population, therapies designed to target stem cells in tumors are predicted to effect more long-standing

remissions or cures. Recent data indicating that vitamin D signaling reduces the viability of breast cancer stem cells has generated considerable interest as discussed below.

## 2. Observational and interventional studies on vitamin D and breast cancer

### 2.1 Overview of population studies

Assessment of vitamin D status in relation to breast cancer or other age-related chronic diseases is complicated by difficulties in accurately assessing intake from food and supplements and in estimating the amount of vitamin D generated through sunlight exposure. Known confounders include lifestyle, latitude, pollution, sunscreen, skin pigmentation, genetics, body mass index (BMI), and age. For breast cancer, the influence of reproductive history, menopausal status, and the use of hormone replacement therapies are also critical modifiers of risk. Supplementation studies to assess cancer prevention require large numbers of participants and a long duration of follow-up to ensure sufficient cancer cases for stratification by cancer subtype. The ideal protocol would include an assessment of serum 25(OH)D at baseline and in response to supplementation. Despite these caveats, observational studies, meta-analyses, and supplementation studies have provided support for the beneficial effects of vitamin D in reducing cancer risk as discussed below and summarized in Table 88.1.

**TABLE 88.1** Vitamin D and breast cancer: observational data and intervention trials.

References	Study design	Outcomes
<i>UVR and breast cancer incidence</i>		
Hiller et al. 2020 [14]	Meta-analysis of 13 studies that evaluated self-reported solar UVR exposure in relation to breast cancer risk.	Breast cancer risk decreased for women spending $\geq 1$ h/d in the sun versus $< 1$ h/d. Evident for lifetime or usual adult exposure as well as exposure during adolescence.
Gregoire et al. 2022 [15] Sister study	Prospective population study of 48,450 US women; UVR exposure estimated with spatiotemporal kriging models based on enrollment address.	UVR exposure inversely associated with risk of ER– (but not ER+) breast cancer. Effect limited to non-hispanic white women not taking vitamin D supplements.
<i>25(OH)D and breast cancer incidence</i>		
Estebanez et al. 2018 [16]	Meta-analysis. 29 case–control studies; four cohort studies.	Inverse relationship between 25(OH)D and breast cancer incidence, especially in premenopausal women. Breast cancer incidence is not associated with dietary vitamin D, use of vitamin D supplements or 1,25(OH) <sub>2</sub> D.

*Continued*

**TABLE 88.1** Vitamin D and breast cancer: observational data and intervention trials.—cont'd

References	Study design	Outcomes
Song et al. 2019 [17]	Meta-analysis. 44 case–control studies; six cohort studies. Assessed dose–response relationship.	Breast cancer risk inversely related to serum 25(OH)D: 5 nmol/L increase of serum 25(OH)D was associated with 6% decrease in breast cancer risk.
<i>25(OH)D and breast cancer outcome</i>		
Vaughan-Shaw et al. 2017 [18]	Meta-analysis (all cancers) 38 studies for overall survival; 23 studies for disease progression.	For breast cancer, serum 25(OH)D level inversely related to overall survival (HR = 0.75) and disease progression (HR = 0.66). Limited evidence for genetic variability to affect survival.
<i>Vitamin D supplementation trials</i>		
Manson et al. 2019 [19] VITAL trial NCT01169259	Men (≥50 years), women (≥55 years). Vit D: 12,927; Placebo: 12,944. Oral vitamin D 2000 IU/d.	5 years vitamin D supplementation did not decrease incidence of new cancers. Not powered to stratify for specific cancer types.
Chandler et al. 2020 [20] VITAL trial NCT01169259	Men (≥50 years), women (≥55 years). Vit D: 3884; Placebo: 3959. Oral vitamin D 2000 IU/d.	Vitamin D supplementation decreased incidence of advanced and fatal cancers; limited to those with healthy BMI.
Peila et al. 2021 [21] WHI trial NCT 00000611	Postmenopausal women. Vit D: 16,753; Placebo: 16,601. Oral vitamin D (400 IU/d) with calcium (1000 mg). Intervention phase = 7.1 years; Postintervention phase = 13.8 years.	18.0% reduced risk of DCIS with vitamin D supplementation in the postintervention period (HR = 0.76).
Bischoff-Ferrari 2022 [22] DO HEALTH trial NCT01745263	Men & women ≥70 years. Oral vitamin D (2000 IU/d), omega-3 fatty acids (1 g/d), and/or exercise versus placebo 3 years follow-up.	Vitamin D alone reduced risk of total cancer (HR = 0.76). Cumulative cancer risk reduction with all 3 interventions (HR = 0.39).
Scragg et al. 2019 [23] VIDA trial ACTRN12611000402943	Men and women (50–84 years). VitD: 2513; Placebo: 2491. Oral vitamin D: Initial bolus dose of 200,000 IU, then 100,000 IU monthly versus placebo.	Monthly high-dose vitamin D supplementation did not decrease incidence of new in situ or invasive cancers over 3.3 years median follow-up.
Arnaout et al. 2019 [24] NCT01948128	Newly diagnosed breast cancer patients. VitD: 43; Placebo: 37. 40,000 IU/day 2–6 weeks prior to surgery.	High-dose vitamin D supplementation did not alter biomarkers of proliferation or apoptosis in primary tumor tissue.

## 2.2 Ultraviolet radiation (UVR) exposure and breast cancer risk

Observational studies have suggested that the incidences of several types of cancer are correlated with latitude and elevation, leading to the hypothesis that populations near the equator attain higher vitamin D status which delays or suppresses tumor development. As will be discussed in more detail in later sections, this hypothesis is supported by cellular and animal studies which have consistently demonstrated anti-tumor effects of 1,25dihydroxyvitamin D (1,25(OH)<sub>2</sub>D). Early large international studies demonstrated inverse correlations between incident solar radiation and cancer

rates as discussed in recent reviews [25,26]. In studies that have specifically assessed indices of cutaneous vitamin D synthesis (such as time spent outdoors, ambient/residential UVR, and/or skin pigmentation), about half have reported significant reductions in breast cancer incidence as a function of sunlight exposure, consistent with risk reduction in those with high vitamin D production. However, in some studies, these associations were limited to certain population subgroups and disease subtypes or dependent on the region of residence or skin type [27,28]. A large (>35,000 women) study which comprehensively analyzed sun sensitivity, time spent outdoors, and ambient UVR during five life

periods failed to detect a correlation between UVR and breast cancer incidence [29]. In contrast, a study of >38,000 Danish women indicated that after the age of 50 years, longer duration of UVR exposure ( $\geq 20$  years: OR = 0.83, 95% CI 0.75–0.92) and highest cumulative exposure (OR = 0.89, 95% CI 0.83–0.95) were inversely associated with risk [30]. A meta-analysis of 13 studies of self-reported measures of solar UVR exposure [14] reported a decreased risk of breast cancer for individuals spending  $\geq 1$  h per day in the sun during summer months over a lifetime versus those with lower exposure [pooled relative risk of 0.84]. Interestingly, exposure during adolescence (a critical developmental period for the breast) was more suggestive of a lower risk of breast cancer than exposure later in life. Data from the US Sister study (3500+ breast cancer diagnoses over 10+ years follow-up) which was not included in the meta-analysis demonstrated that residential UV exposure was inversely related to risk for ER– but not ER+ breast cancer [15]. The inconsistent results from various studies may be related to not only dose and duration of UVR exposure in relation to disease onset, but also genetics and physiological factors that modify an individual's ability to synthesize, store or utilize cutaneously-derived vitamin D. In addition to pigmentation, aging has long been known to reduce the epidermal synthesis of vitamin D [31] and mouse studies have recently demonstrated gender differences in UVB-induced vitamin D production related to androgen regulation of 7-dehydrocholesterol concentrations in the skin [32]. Therefore, there are likely multiple physiological and genetic factors that influence cutaneous vitamin D production. A better understanding of the regulation of vitamin D synthesis in the skin will be necessary to resolve the discrepancies in these population studies. In addition, when significant associations between UVR exposure and biological effects are observed, it remains important to distinguish the degree to which such associations result from vitamin D-dependent actions since UVR exerts vitamin D-independent effects as well.

### 2.3 Serum 25(OH)D and breast cancer risk

Observational studies designed to directly address the impact of vitamin D status from multiple sources, as measured by serum 25-hydroxyvitamin D (25(OH)D), on breast cancer incidence have also yielded mixed results. Several studies have supported the concept that high serum 25(OH)D is associated with decreased risk of breast cancer development [33–37], longer disease-free survival, or reduced mortality [38–40], while others have found significant correlations restricted to certain subgroups (i.e., postmenopausal women, younger subjects, ethnicity) and yet others

have demonstrated weak, nonsignificant inverse correlations or no associations [41–45]. A few of the most recent studies will be briefly reviewed here. Eliassen et al. [46] conducted a follow-up analysis of the Nurses Health Study that included >1500 breast cancer cases and controls, and while no association was found between 25(OH)D and breast cancer overall, there was a significant inverse correlation in women whose blood was sampled in summer. In a meta-analysis of 68 studies published between 1998 and 2018 [16], a protective effect of serum 25(OH)D (but not vitamin D intake or serum 1,25(OH)<sub>2</sub>D) on breast cancer risk was observed in both cohort studies (RR = 0.85, 95%CI:0.74–0.98) and case-control studies (OR = 0.65, 95%CI: 0.56–0.76). In a meta-analysis designed to evaluate the dose-response relationship between 25(OH)D and breast cancer risk, Song et al. calculated that an increase in serum 25(OH)D by 5 nmol/L was associated with a 6% decrease in breast cancer, with equal effects in pre- and postmenopausal women [17]. In contrast, some studies have found that the association between 25(OH)D and breast cancer risk was limited to pre-menopausal women [16]. Related to this observation, Cadeau et al. [47] conducted subgroup analysis of the French E3N cohort (>55,000 women and >2400 breast cancer cases) to evaluate potential interactions between vitamin D supplement use and hormone replacement therapy (HRT). While serum 25(OH)D was not measured, the use of vitamin D supplements was found to be protective against breast cancer in women who had taken HRT. Surprisingly, the opposite effect (increased risk) was observed with vitamin D supplementation in women who had never used HRT.

The relationship between vitamin D status and the risk of breast cancer in African Americans and other populations with a high frequency of vitamin D deficiency/insufficiency due to genetic or cultural factors has been understudied. In a multi-ethnic cohort, an inverse relationship between serum 25(OH)D and breast cancer was found in Caucasian women but not other racial groups including African-Americans [34]. In the Sister study, with a mean follow-up of 9.2 years, women with circulating 25(OH)D concentrations above the clinical cut point for deficiency (20.0 ng/mL) had lower breast cancer rates than women with concentrations  $\leq 20$  ng/, and the inverse association was strongest among Hispanic/Latina women, with a weaker association observed among Black/African American women [48]. However, the inverse association between the recent use of vitamin D supplements and breast cancer risk was similar in African American/Black and non-Hispanic White populations [49]. In a small case-control study of Iranian women, another ethnic population at high risk for vitamin D deficiency, subjects in the fourth quartile of serum 25(OH)D level

had threefold lower risk of developing breast cancer compared to those in the first quartile, but in this population, the relationship was observed in premenopausal but not postmenopausal women [50]. Prospective analysis of the Black Women's Health Study used a validated prediction model to assess cumulative serum 25(OH)D in relation to breast cancer. This data showed that 45% of participants were categorized as vitamin D deficient (<20 ng/mL) or insufficient (20–29 ng/mL) and that breast cancer risk significantly increased with decreasing quartile of predicted 25(OH)D<sub>3</sub> [51]. Further analysis of this population is of interest since it is not clear how well predictive models reflect actual serum 25(OH)D<sub>3</sub> levels [52]. Collectively, these selected studies highlight many of the factors that modify the relationship between vitamin D status and breast cancer including seasonality, ethnicity/race, menopausal status, and HRT use. These and other factors such as study size and analytical methods likely account for the diverse conclusions in population studies.

## 2.4 Serum 25(OH)D and breast cancer aggressiveness/survival

Shirazi et al. [53] assessed the association of vitamin D with breast cancer aggressiveness through analysis of serum 25(OH)D from >750 incident breast cancer cases and matched control subjects in the Malmo Diet and Cancer Study. They found that women with prediagnostic serum levels of 25(OH)D between 77 and 97 nmolar had the lowest risk of developing aggressive tumors (i.e., ER and PR negative, high mitotic index). Of note, women with serum 25(OH)D<sub>3</sub> <76 or >98 nmolar were significantly more likely to develop tumors with unfavorable prognosis, suggestive of bi-phasic effects of vitamin D status on disease progression. Further analysis of this cohort after mean follow-up of 13.1 years was conducted to assess the impact of prediagnostic serum 25(OH)D and tumor VDR expression [54]. Only patients with invasive breast cancer without bilateral disease or distant metastases and who did not undergo treatment were included (691 controls and 497 breast cancer cases). Women with VDR-positive tumors exhibited better survival especially when prediagnostic serum 25(OH)D was in the lowest tertile. Consistent with these reports, a systematic review and meta-analysis of vitamin D status and cancer survival (which included breast cancer cases), reported longer progression-free survival and reduced risk of death in those with high compared to low 25(OH)D levels [18]. Within the last several years, the adverse impact of vitamin D deficiency on survival of breast cancer patients has been confirmed in five

additional studies using various approaches [9,55–58]. Perhaps more clinically relevant, a beneficial effect of vitamin D status on disease recurrence after anti-endocrine therapy for ER+ breast cancer was reported by Lim et al. [59]. A striking increase in the incidence of late recurrences (particularly in regional lymph nodes, bone, and visceral sites) was observed in patients categorized as vitamin D deficient (serum 25(OH)D < 20 ng/mL) at the end of the standard 5-year course of endocrine therapy. Overall, the consistency of data linking low serum 25(OH)D with disease aggressiveness and poor survival warrant intervention studies to determine whether increasing vitamin D status after diagnosis will slow disease progression. Given there are >4 million breast cancer survivors in the US alone, a beneficial effect of vitamin D in this population would have a substantial translational impact.

## 2.5 Vitamin D and breast cancer subtypes

As discussed above, genomic studies have demonstrated that breast cancers are heterogeneous and that different subtypes exhibit distinct patterns of disease progression. It is likely that VDR expression or function and thus sensitivity to changes in vitamin D status may be subtype-specific, yet this has not rigorously been examined. The limited epidemiologic data that has been stratified by subtype is mixed. Yao et al. [60] conducted case-control and case series analyses and found that the relationship between serum 25(OH)D and reduced risk of breast cancer was strongest for high-grade, ER-negative, and triple-negative cancers. This finding is supported by the Malmo study cited above [53] which found a higher incidence of ER and PR tumors in women with low serum 25(OH)D. In contrast, Kim et al. [61] reported that low serum 25(OH)D was associated with poor prognosis only in women with the luminal subtype of breast cancer.

Qin et al. [62] conducted a case-control study to assess the association between vitamin D and breast cancer subtypes among African-American/black women, who tend to develop more aggressive forms of the disease. Evaluation of diet, supplement use, and sunlight exposure in 1724 cases (1213 ER+, 511 ER–, and 335 TNBC) and 1233 controls suggested that a moderate intake of supplemental vitamin D (up to 800 IU/day, but not >800 IU/day) was associated with decreased risk of several breast cancer subtypes, with effects that appeared strongest for TNBC. More sunlight exposure was also associated with decreased risk of both the ER– and TNBC subtypes in this population. These associations were not altered by menopausal status or obesity.

## 2.6 Vitamin D supplementation trials for breast cancer prevention

The gold standard tests for the effectiveness of cancer preventive agents are the large randomized controlled trials (RCT) in which healthy subjects receive either the proposed chemoprevention regimen or a placebo. Although many RCTs of vitamin D supplementation have been conducted, most have been designed to assess end points other than cancer and thus have not been sufficiently powered nor of long enough duration for meaningful results with respect to the development of a low incidence, heterogeneous disease that develops slowly such as cancer. The first large RCT designed to assess the impact of vitamin D supplementation on cancer end points was the Women's Health Initiative (WHI). This study recruited >30,000 postmenopausal women to a supplement containing calcium (1000 mg) and vitamin D (400 IU) or a placebo for an average duration of 7–11 years. This trial was confounded by the low dose of vitamin D utilized, the coadministration of calcium supplements, poor compliance, extensive pre-trial supplement use in the study population, and the freedom for trial participants to take additional personal supplements of up to 1000 IU vitamin D per day. The initial WHI results indicated no significant effect of vitamin D plus calcium supplementation on breast cancer or other endpoints such as colon cancer and cardiovascular disease. Subgroup and follow-up analyses of trial participants have yielded mixed results. One follow-up analysis [63] after a mean of 10 years that also analyzed dietary vitamin D indicated that higher intake of vitamin D was associated with a lower risk of premenopausal breast cancer (hazard ratio in the highest quartile compared to the lowest was 0.65). An inverse association between vitamin D intake and the incidence of large or poorly differentiated breast tumors was also detected among premenopausal women. However, no associations were identified in postmenopausal women. In another analysis of 15,646 women in the WHI cohort who were not taking personal calcium or vitamin D supplements at randomization, calcium plus vitamin D supplementation significantly decreased the risk of total cancers, all breast cancers, and invasive breast cancers by 14%–20% [64]. Recent analysis of the WHI study participants after 20+ years follow-up revealed a significant reduction in the incidence of DCIS in the calcium and vitamin D cohort [21], with the biggest effect observed in participants who also took personal vitamin D supplements during the intervention period. This later finding is noteworthy for two reasons. First, it suggests that vitamin D status may affect the earliest stage of breast cancer as DCIS is considered a preneoplastic condition. Second, the additive impact of personal supplement use in the intervention cohort indicates that the

low study dose (400 IU/day) did not optimize serum 25(OH)D for the prevention of early-stage cancer. Consistent with these findings, O'Brien et al. [49] reported a strong inverse association between the recent use of vitamin D supplements and DCIS in the Sister study. Collectively, these findings have enormous translational potential as more than 50,000 women are diagnosed with DCIS annually in the US alone [65].

In 2019, results from the Harvard-based VITAL trial of 20,000 US men (>50 years) and women (>55 years) randomized to daily supplements of 2000 IU vitamin D or placebo for 5 years were reported. Initial analysis of the VITAL study showed no significant effect of vitamin D supplementation on total cancer development, but a possible reduction in fatal cancers [19]. In secondary analysis [20] a significant reduction in metastatic and fatal cancers was found for those randomized to vitamin D compared with placebo (Hazard Ratio = 0.83). When stratified by BMI, there was a significant reduction for the vitamin D arm in incident metastatic or fatal cancer among those with normal BMI but not among those categorized as overweight or obese. The effect of vitamin D supplementation on advanced cancers was not modified by baseline serum 25(OH)D level or self-identified race category. Due to the relatively short duration of this trial, the number of cases was inadequate to stratify by cancer type, although the biggest effect of vitamin D supplementation appeared to be for the reduction of advanced/fatal prostate cancer.

In a smaller trial on cancer incidence (DO-HEALTH), 2157 European men and women over 70 years of age were randomized to either vitamin D (2000 IU/day), omega-3 fatty acids, an exercise program, or all three interventions [22]. After 3 years of follow-up, vitamin D supplementation significantly reduced the incidence of all cancers (Hazard Ratio = 0.76) and breast cancer (Hazard Ratio = 0.83). Further risk reduction was observed when vitamin D was combined with omega-3 or exercise and the lowest risk was in those assigned to all three interventions (Hazard Ratio = 0.26) [22].

Two additional supplementation trials are worth mentioning. The New Zealand-based ViDA trial [23] randomized ~5000 men and women (50–84 years) to monthly high-dose vitamin D (initial bolus dose of 200,000 IU followed by 100,000 IU monthly) or placebo for 3.3 years. No beneficial effect of vitamin D supplementation on new in situ or invasive cancers was observed over the relatively short time frame. It should be noted that many factors modify the impact of bolus doses [66] and their use is controversial [67]. Another recent trial [24] addressed whether high-dose vitamin D supplementation (40,000 IU/d) for newly diagnosed patients during the short time period between diagnosis and surgery would alter cell turnover in the breast

tissue. No significant differences in tumor cell proliferation or apoptosis were detected in breast tissues removed at surgery, possibly due to the unusually high dose, small number of patients, heterogeneity of disease, and/or variable duration of supplementation. However, additional studies of this nature are warranted to determine if the time period between diagnosis and surgery is a window of opportunity for vitamin D supplementation with respect to disease prognosis.

## 2.7 Summary of observational and intervention studies

As summarized in Table 88.1, recent studies have provided considerable support that low vitamin D status is associated with increased risk for breast cancer, more aggressive disease and reduced survival. It should be noted that while vitamin D deficiency is common in all breast cancer patient populations, it is particularly prevalent in those with triple negative/basal-like tumors, the most aggressive form of the disease [68–70]. Although progress has been made in clarifying the impact of vitamin D supplementation on breast cancer, continued follow-up of the cohorts described above (especially the VITAL population) is clearly warranted. Even in the absence of rigorous “proof” of the beneficial effect of supplemental vitamin D on breast cancer, correction of vitamin D deficiency in women at risk for, or living with, breast cancer should be standard practice.

## 3. Expression and function of the vitamin D pathway in normal and neoplastic breast cells/tissues

### 3.1 VDR expression and function in normal mammary gland

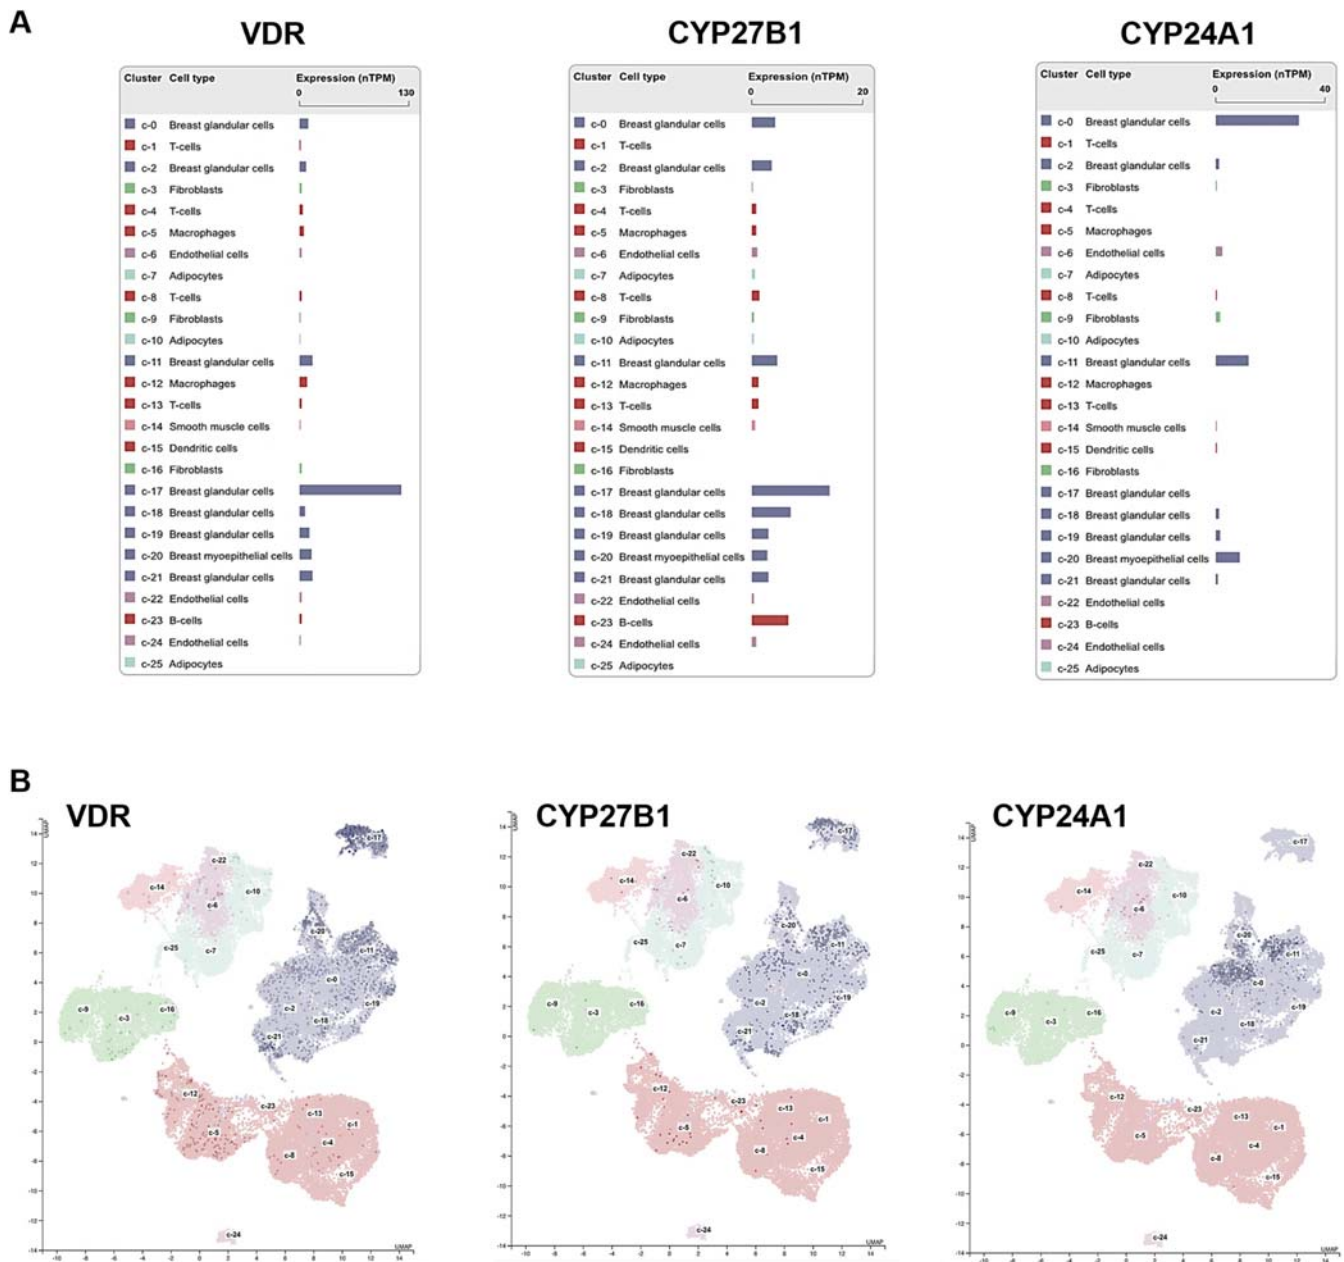

The VDR has been detected in rat, mouse, and human mammary glands and its expression is highest during puberty, pregnancy, and lactation [71,72]. High content immunohistochemistry of normal human breast epithelium demonstrated that VDR was expressed in nonproliferating, differentiated luminal cells and partially co-localized with ER [12]. We mapped VDR mRNA expression in various cell types of the normal adult human breast using a single-cell RNA-seq dataset [73]. As shown in Fig. 88.1A, VDR expression is highest in the eight cellular clusters representative of the epithelial compartment (highlighted in purple). VDR expression is particularly enriched in c-17, a cluster defined by expression of beta-casein (CSN2). As the major protein component of milk, beta-casein also binds and transports calcium into milk. Co-localization of VDR with CSN2 in secretory luminal epithelial cells is consistent

with the study of Santagata (12) cited above and suggests a role for VDR in lactation (further discussed below). VDR is detected at low levels in stromal and immune cell types (pink, red, and green clusters in Fig. 88.1A), consistent with published reports [74–76] and highlighting the potential complexity of 1,25(OH)<sub>2</sub>D signaling in the breast tissue environment.

Studies on the vitamin D pathway in the murine mammary gland have revealed an important role in the vitamin D pathway during development (Table 88.2). A distinct gradient of VDR protein expression was observed during the pubertal development of the mouse mammary gland, with weak VDR staining in proliferative populations and strong VDR staining in differentiated populations [72]. The role of the *Vdr* in mammary ductal morphogenesis was examined in *Vdr* knockout (VDRKO) mice fed high dietary calcium which normalizes fertility and neonatal growth [72]. During puberty, mammary glands from virgin VDRKO mice were heavier and exhibited accelerated growth, as evidenced by higher numbers of terminal end buds, greater ductal outgrowth, and enhanced secondary branching compared with glands from age- and weight-matched wild-type mice. In addition, glands from VDRKO mice exhibit enhanced growth in response to exogenous estrogen and progesterone, both in vivo and in organ culture, compared with glands from wild-type mice. 1,25(OH)<sub>2</sub>D inhibited growth and side branching of glands from wild-type mice but not VDRKO mice. More recent studies have implicated autophagy as a vitamin D-regulated pathway in the mammary gland [82]. Both dietary vitamin D and deletion of the VDR significantly modulated basal levels of autophagy in the murine mammary gland in the absence of hypercalcemia. These data provided convincing in vivo evidence that 1,25(OH)<sub>2</sub>D and the VDR impact ductal elongation, branching morphogenesis, and tissue homeostasis in the mammary gland.

Given the expression of VDR in multiple cell types in the gland, the effects of selective *Vdr* ablation in epithelial and adipose cells have been evaluated. Johnson et al. [79] reported that deletion of *Vdr* in either cellular compartment accelerated ductal morphogenesis in association with increased proliferation and decreased apoptosis within terminal end buds. VDR signaling in the mammary epithelium modulated estrogen- and progesterone-induced alveolar growth, as ablation of *Vdr* in this cell type resulted in precocious alveolar development. Ex vivo studies demonstrated that ligand-dependent VDR signaling in adipocytes inhibited mammary epithelial cell growth in part through 1,25(OH)<sub>2</sub>D-dependent production of the cytokine *IL-6* [79]. Subsequently, Matthews et al. [83] studied adult mice with adipose-specific *Vdr* deletion reared on high-fat diets and reported enhanced mammary

**FIGURE 88.1** Single cell analysis of VDR, CYP27B1, and CYP24A1 mRNA expression in human breast tissue.

epithelial density and branching relative to control animals. These data support the hypothesis that VDR in mature adipocytes alters the metabolic response to high-fat diets and exerts antiproliferative effects on the mammary epithelium. Collectively, these results suggest that vitamin D signaling contributes to growth inhibition of the mammary gland through independent actions in epithelial and stromal (adipose) compartments.

The role of VDR during lactation is poorly understood. Although *Vdr* remains highly expressed throughout pregnancy and lactation, neither glandular morphology nor milk calcium content was affected by

*Vdr* deletion in mice [77]. A caveat to these results is that VDRKO mice are typically reared on high-calcium diets which may facilitate calcium transport across mammary secretory cells in the absence of the receptor. A direct role for  $1,25(\text{OH})_2\text{D}$  in the regulation of calcium transport into milk was recently demonstrated in an in vitro model of secretory mammary epithelial cells [84].  $1,25(\text{OH})_2\text{D}$  increased the expression of genes encoding proteins involved in calcium and glucose transport (Calbindin D9K, PMCA1b, PMCA2b, GLUT1, and GLUT12) as well as the activities of several enzymes involved in these processes (hexokinase, CaMg

**TABLE 88.2** Animal studies on vitamin D pathway in mammary gland and breast cancer.

Model	Outcome
<b>Development, aging, spontaneous tumorigenesis</b> <b>Mice with targeted deletion of vitamin D pathway genes</b>	
Wild-type (WT) and <i>Vdr</i> knockout (VDRKO) mice maintained on rescue diet: mammary development and aging studies [72,77,78].	High VDR expression in differentiated epithelial cells of WT mice. Increased hormone-stimulated proliferation and branching in VDRKO glands in organ culture and in vivo compared to WT mice. Delayed glandular regression after lactation in VDRKO relative to WT mice.
Mammary epithelial- or adipocyte-specific <i>Vdr</i> KO: development study [79]	VDR in both adipose and epithelial cells functions to restrict pubertal glandular proliferation/development. Epithelial VDR (but not adipose VDR) functions to restrict alveologenesis during pregnancy. 1,25D induced secretion of IL-6 and leptin via adipose VDR ex vivo.
WT and <i>Cyp27b1</i> knockout (CYP27B1KO) mice: aging study [80].	Increased age-related spontaneous tumor burden in CYP27B1KO mice compared to WT mice. Prevented by either 1,25D or antioxidants, implying that lack of 1,25D enhanced oxidative stress and DNA damage. Mechanistic data implicated HGF and MET receptor in driving tumorigenesis.
Mammary epithelium specific deletion of <i>Cyp24a1</i> : Development study [81].	<i>Cyp24a1</i> deletion in mammary epithelium reduced proliferation and inhibited ductal budding, outgrowth, and branching (at puberty) and alveologenesis (in early pregnancy).
<b>Chemically induced mammary tumorigenesis</b> <b>Mice exposed to DMBA (dimethylbenzanthracene) develop mammary tumors that express ER and PR</b>	
WT and VDRKO mice fed high calcium rescue diet were evaluated for glandular morphology and mammary tumorigenesis after DMBA treatment [151].	Tumor incidence was near 100% in both WT and VDRKO mice, but VDRKO tumors were predominantly negative for ER and PR and exhibited trans-differentiation toward epidermis and hair. Glands from VDRKO mice showed impaired proliferative response to MPA stimulation compared to WT mice. Tumor histology in VDRKO mice was suggestive of <i>wnt</i> pathway activation.
Tumor incidence and burden were evaluated in mice fed AIN93G diets with standard or supplemental vitamin D prior to DMBA treatment [105].	Mice fed 25,000 IU/kg vitamin D had decreased tumor incidence and burden compared to those fed 1000 IU/kg. High dietary vitamin D inhibited pro-survival autophagy markers and increased the accumulation of p62. Tumor autophagy was reduced with vitamin D supplementation.
<b>Xenograft and allograft models</b> <b>Human or murine breast cancer cells injected into murine hosts at various sites to mimic primary tumor progression and/or metastatic colonization.</b>	
Mammary tumor cells isolated from DMBA-induced tumors generated in WT and VDRKO mice were grown as grafts in mice treated with EB1089 or exposed to UV radiation [133].	Chronic UV exposure increased serum 25(OH)D in tumor-bearing mice. EB1089 and UV exposure inhibited growth of xenografts containing <i>Vdr</i> <sup>+</sup> but not <i>Vdr</i> <sup>-</sup> tumor cells. Both treatments induced growth arrest and apoptosis in <i>Vdr</i> <sup>+</sup> but not <i>Vdr</i> <sup>-</sup> tumors.
MMTV-wnt1, 168-FARN, and 4T1 tumor grafts in immune competent Balb/c mice [135].	MMTV-wnt1 tumors grew faster in mice fed 25IU vitamin D/kg versus those fed 500 IU/kg. shRNA-mediated knockdown of <i>Vdr</i> in 168-FARN cells increased growth and metastasis while re-expression of <i>Vdr</i> reversed these effects. ID1 was identified as a VDR repressed gene in both vitamin D deficiency and <i>Vdr</i> knockdown studies.

**TABLE 88.2** Animal studies on vitamin D pathway in mammary gland and breast cancer.—cont'd

<b>Xenograft and allograft models</b>	
<b>Human or murine breast cancer cells injected into murine hosts at various sites to mimic primary tumor progression and/or metastatic colonization.</b>	
TM40D murine xenografts implanted into WT and CYP27B1KO mice [80].	Enhanced growth of xenografts in CYP27B1KO versus WT mice; with increased oxidative stress and DNA damage and tumor cellular senescence. Potential mediators HGF, c-MET, BMI1.
Orthotopic tumors derived from MDA-MB-231 TNBC cells expressing control or <i>CYP24A1</i> targeted shRNA [136].	Suppression of <i>CYP24A1</i> in MDA-MB-231 tumors reduced tumor weight, proliferation, and vascularity while enhancing apoptosis and necrosis. Gene expression profiling was conducted in MCF-7 and MDA-MB-231 cells upon <i>CYP24A1</i> silencing in vitro.
Comparison of skeletal metastases after intracardiac injection of MDA-MB-231 TNBC cells [181].	shRNA-mediated knockdown of <i>VDR</i> in injected tumor cells promoted epithelial-mesenchymal transition, cancer cell mobility (migration), and invasiveness, thereby facilitating skeletal colonization.
Growth and immune landscape in E0771 (murine luminal B-like) syngeneic xenografts in C57BL/6 mice [142].	Vitamin D supplementation (40 IU/mouse/day by gavage) slowed tumor growth, promoted CD8 <sup>+</sup> T cell infiltration, decreased systemic inflammatory cytokines, and reduced M1 macrophages in adipose depots. Obesity reversed the effects of vitamin D supplementation.
Growth of 4T1 (murine TNBC-like) xenografts in immune competent Balb/c mice [240].	Vitamin D supplementation (5 ug every other day) increased tumor burden which was abrogated by exercise training.
Growth and metastasis of 4T1 (murine TNBC-like) and E0771 (murine luminal B-like) xenografts in immune competent Balb/c and C57BL/6 mice [145,146].	Vitamin D supplementation tended to reduce growth of primary tumors composed of E0771 cells but not 4T1 cells. 1,25(OH) <sub>2</sub> D treatment or vitamin D supplementation increased lung metastasis of 4T1 but not E0771 xenografts. In contrast, vitamin D deficiency tended to increase metastasis of both E0771 and 4T1 xenografts. Refer to publication for comprehensive data on vitamin D metabolites in these models.
Combination of vitamin D analogs and an aromatase inhibitor [241].	PRI-2191 or PRI-2205 (noncalcemic vitamin D analogs) potentiated the antitumor effects of anastrozole in MCF-7 tumor-bearing mice. Combination treatment reduced aromatase gene expression and activity and down-regulated ER expression.
Combination of 1,25(OH) <sub>2</sub> D with tyrosine kinase inhibitors [214,242].	Additive or synergistic effects of 1,25(OH) <sub>2</sub> D with the kinase inhibitors dovitinib (cKIT, FGFR, VEGFR) and Ruxolitinib (JAK) in various breast cancer xenograft models:
Combination of 1,25(OH) <sub>2</sub> D with menadione (synthetic vitamin K) [243].	In murine transplantable triple negative breast tumor M-406, 1,25(OH) <sub>2</sub> D plus menadione reduced tumor growth rate and increased apoptosis more effectively than individual agents without weight loss.
Combination of 1,25(OH) <sub>2</sub> D with phytochemicals curcumin and resveratrol [237].	Antitumor effects of 1,25(OH) <sub>2</sub> D were enhanced in combination with curcumin or resveratrol in human MBCDF-T xenografts, primarily through inhibition of tumor angiogenesis.
<b>Transgenic models</b>	
<b>Engineered expression of hormones or oncogenes drive mammary tumorigenesis</b>	
<b>bLHβ-CTP mice:</b> Mammary hyperplasia and spontaneous tumors develop in response to chronic, systemic LH production [244].	LH-driven tumors had high <i>Vdr</i> expression. Tumor bearing mice were treated with VDR agonist EB1089. EB1089 inhibited tumor cell proliferation and reduced tumor burden in ~50% of treated mice.
<b>MMTV-NEU mice:</b> Mammary-epithelial expression of <i>Neu</i> oncogene induces stochastic tumors over prolonged time course [148].	Tumor bearing mice were treated with VDR agonist BXL0124. BXL0124 decreased tumor weight, incidence and multiplicity and inhibited ERBB2, ERK, and AKT signaling.

TABLE 88.2 Animal studies on vitamin D pathway in mammary gland and breast cancer.—cont’d

Transgenic models	
Engineered expression of hormones or oncogenes drive mammary tumorigenesis	
MMTV-NEU mice were treated with VDR agonist BXL0124 ± CDDO-Im (synthetic triterpenoid) either before or after tumor onset [147].	In prevention protocol, both BXL0124 and CDDO-Im delayed tumor development but the combination was most effective. In the therapeutic protocol, administration of the combination did not reduce tumor burden.
MMTV-PyMT mice: Mammary-epithelial expression of polyoma middle T antigen rapidly induces mammary tumors that metastasize to lung [149,245].	Low dietary vitamin D (25 IU/kg) accelerated tumorigenesis relative to standard diet (1000 IU/kg). Systemic perfusion with 25(OH)D or 1,25(OH) <sub>2</sub> D delayed tumorigenesis. Both 25(OH)D and 1,25(OH) <sub>2</sub> D accumulated in tumors. Vitamin D deficiency enhanced signaling through CXCL12/CXCR4 in lung metastatic niche and increased expression of pSTAT3 and ZEB1.
MMTV-PyMT mice were crossed with mice bearing mammary-specific deletion of <i>Cyp27b1</i> [150].	Targeted ablation of CYP27B1 in MMTV-PyMT mice accelerated mammary hyperplasia and tumorigenesis. NfκB and JAK-STAT signaling were increased in <i>Cyp27b1</i> ablated tumors. <i>Cyp27b1</i> ablation reduced tumor 1,25(OH) <sub>2</sub> D content.
MMTV-NEU mice: MMTV-NEU mice were crossed with VDRKO mice to generate WT, heterozygous (HET) and KO offspring bearing the <i>Neu</i> transgene [152].	Strong expression of VDR was detected in MMTV-NEU tumors and lung metastatic foci. Abnormal ductal morphology observed in VDRKO and VDR-HET mice. Poor long-term survival of VDRKO mice occurred due to weight loss and skin lesions. MMTV-Neu tumor incidence was increased in VDRHET versus WT mice.

ATPase, NaK ATPase). These data suggest the possibility that 1,25(OH)<sub>2</sub>D may enhance calcium transport into milk during lactation, but only when energy reserves are sufficient. Wagner’s group, who has pioneered studies on the effects of vitamin D supplementation during human pregnancy and lactation, has demonstrated correlations between maternal vitamin D status and milk composition, particularly with respect to cytokines and immune function [85,86].

A unique phenotype was observed in the mammary gland of aging VDRKO mice by Welsh et al. [78]. In contrast to the accelerated growth of the gland during puberty and pregnancy, atrophy of the mammary gland was observed in 12–16 month-old VDRKO mice. Relative to wild-type aged matched controls, VDRKO mice exhibited ductal ectasia of the primary mammary ducts, loss of secondary and tertiary branches, and atrophy of the adipose tissue due to activation of apoptosis. These morphological changes in the glands of aged VDRKO mice were associated with ovarian failure and reduced serum 17β-estradiol despite the maintenance of normocalcemia with the high calcium rescue diet. Subsequent

studies indicated that VDRKO mice exhibit a lean phenotype, resistance to obesity, and enhanced energy expenditure, suggesting that the mammary phenotype during aging may reflect long-standing systemic consequences of *Vdr* ablation [87]. It is unclear whether vitamin D status modulates the aging process in the human mammary gland.

### 3.2 Local metabolism of vitamin D in mammary gland

In addition to *Vdr*, the 25(OH)D metabolic enzyme *Cyp27b1* is detected in murine and human mammary tissue [77,88–90] suggesting that systemic 25(OH)D delivered to the mammary gland can be converted to the biologically active VDR ligand 1,25(OH)<sub>2</sub>D. In the single-cell analysis of a normal human breast, *CYP27B1* expression is enriched in c-17 (the epithelial cluster with the highest expression of VDR) and strongly co-localizes with VDR overall (Fig. 88.1B). Interestingly, *CYP24A1* expression (Fig. 88.1C) is not detected in c-17,

although its expression overlapped with *VDR* and *CYP27B1* in most other clusters. Of note, *CYP24A1* was one of only three genes expressed in luminal progenitor cells isolated from both human and mouse breast tissue, suggesting it may play a unique role in mammary cell lineage determination [91].

Developmentally, *Cyp27b1* expression was highest during mid-pregnancy in mice [77] suggesting that availability of 25(OH)D to the gland at this time may be especially critical. Lack of *Vdr* during pregnancy was associated with accelerated lobuloalveolar development, larger alveolar clusters, and accumulation of secretions in dilated lumens [77]. Although the impact of *Cyp27b1* ablation on glandular development during pregnancy has not been assessed, conditional deletion of *Cyp24a1* in mammary epithelial cells (which would be expected to enhance local 1,25(OH)<sub>2</sub>D accumulation) was associated with reductions in terminal end bud number, ductal outgrowth and branching during puberty as well as alveologenesis at early pregnancy [81]. Collectively, these murine studies support the concept that activation of VDR signaling by locally produced 1,25(OH)<sub>2</sub>D leads to physiologically relevant modulation of the mammary epithelium, particularly during periods of rapid development (puberty, pregnancy).

Consistent with data demonstrating expression of the vitamin D pathway in the mammary gland, *VDR* and *CYP27B1* were highly expressed in primary and immortalized cultures of nontumorigenic human mammary epithelial cells [89,90]. 1,25(OH)<sub>2</sub>D induced the known VDR target gene *CYP24A1* and exerted growth inhibitory effects indicating functional VDR in mammary epithelial cells. Dose-dependent growth inhibition was also observed in cells treated with 25(OH)D suggesting the existence of autocrine vitamin D signaling within the mammary epithelium. In vitro studies confirmed that incubation of mammary epithelial cells with physiological (nanomolar) concentrations of 25(OH)D led to temporal increases in 1,25(OH)<sub>2</sub>D detected in tissue culture media [89]. *CYP27B1* is also expressed in mammary adipocytes, which have been demonstrated to convert 25(OH)D to 1,25(OH)<sub>2</sub>D in organoid culture [76]. In response to 25(OH)D adipocytes secrete diffusible signals that inhibit morphogenesis of the adjacent ductal epithelium [76].

There is still uncertainty regarding how 25(OH)D, which circulates tightly bound to the vitamin D binding protein (DBP), is internalized by nonrenal cells. The presence of megalin and cubilin [92] in mammary epithelial cells indicates that these accessory proteins could mediate uptake of 25(OH)D-DBP complexes in the mammary gland as has been demonstrated for the kidney. Rowling et al. [92] demonstrated that normal breast epithelial cells and some breast cancer cells internalize DBP via megalin-mediated endocytosis. Given

the presence of *CYP27B1* in mammary adipocytes, it is worth noting that preadipocytes also express megalin and internalize 25(OH)D in culture [93]. However, the function of the megalin-mediated uptake pathway for the 25(OH)D-DBP complex in the intact mammary gland has yet to be confirmed.

### 3.3 Evidence for deregulation of the vitamin D pathway in breast cancer

Over 35 years ago, the recognition that VDR expression was detectable in breast cancers prompted extensive studies to determine whether targeting VDR in tumors would provide therapeutic benefit. VDR expression is retained in the majority of rodent breast tumors, human breast cancers, and established breast cancer cell lines [12,71,94,95]. However, some data suggest that receptor protein expression declines in highly aggressive tumors [94–96] and is deregulated by oncogenic transformation as described below [97–99]. It was therefore of interest to evaluate the frequency of genomic VDR changes in The Cancer Genome Atlas (TCGA) datasets of mutations, amplifications, deletions, and mRNA expression profiles in human breast cancers [100]. In this dataset of >450 cases, only 5% of invasive human breast tumors exhibited alterations in *VDR* sequence or expression [101]. However, when the *VDR* gene was altered, the most common change was a reduction in mRNA expression (deletions and mutations were not found). With respect to *VDR* expression in specific molecular subtypes, the highest frequency of alterations was in the Luminal B subtype (10.5% of tumors displayed reduced *VDR* mRNA expression) compared to 0%–3% for Luminal A, Basal, HER2, or Claudin-Low subtypes. The TCGA data showing unmutated *VDR* in the majority of human breast tumors are consistent with that of Santagata et al. [12] who used multiplex immunohistochemistry to map several nuclear receptors at the single cell level and confirmed that most human breast tumors express the VDR protein. In another survey of tumor VDR expression in >1000 patients, 42% of tumors had a negative or low expression, 32% had moderate expression and 25% had strong expression [102].

With respect to tumor VDR expression as a prognostic factor, an early study of 136 patients with primary breast cancer reported that women with VDR-negative tumors relapsed significantly earlier than women with VDR-positive tumors [103]. Consistent with this observation, Santagata et al. [12] reported that breast tumors with the highest expression of VDR, ER, and Androgen Receptor (AR) had the best prognosis [12]. In contrast, in the Al-Azhri study [102] there were no differences in overall survival, progression-free survival, or breast

cancer-specific survival by tumor VDR expression in the whole population or in various subgroup analyses. These discrepancies likely reflect the heterogeneity of VDR expression in breast cancer as well as the potential contribution of an individual's vitamin D status. With respect to the latter, the previously cited study by Huss et al. [54] found a significant association between tumor VDR expression and survival only for patients in the lowest tertile of serum 25(OH)D. As noted above, a subset of tumors express high levels of VDR, and in some datasets, high VDR expression correlates with poor, rather than better, survival [104]. Inherent differences in the populations studied, such as genetics, treatment history or vitamin D status may also contribute to these discrepancies. For example, using four publicly accessible genomic datasets comprising 581 cases, Li et al. [105] demonstrated that higher VDR expression in ER+ tumors predicted significantly longer recurrence-free survival, but only in patients treated with tamoxifen.

### 3.4 Mechanisms of vitamin D resistance in tumor cells

It should be noted that, even when tumors retain VDR expression, its antitumor functions are most likely attenuated. Mechanisms for ineffective VDR signaling include altered receptor function in the absence of mutation, reduced ligand availability, and/or mutation/deregulation of critical downstream VDR targets. Data on receptor expression derived from whole tumors may be somewhat misleading since cancer progression is driven by genetic instability and outgrowth of cells with advantageous mutations, such as the activation of oncogenes. In vitro studies have demonstrated that specific oncogenes can deregulate VDR expression. For example, a comparison of VDR expression in an isogenic mammary cell transformation model indicated that VDR expression and function were reduced by more than 70% in cells expressing SV40 and/or RAS compared to the parental cells [98]. Similar effects of SV40 and RAS on VDR activity have been demonstrated in other breast cancer model systems [97,106]. In addition, transcriptional repressors associated with cancer progressions such as SNAIL and SLUG have been shown to down-regulate VDR [99,107]. With respect to the deregulation of VDR function in gene expression, data from breast, bladder, and prostate cancer support the concept that cancer-associated alterations in transcriptional coregulators can also contribute to altered signaling by the 1,25(OH)<sub>2</sub>D-VDR complex [108,109]. Inhibition of VDR expression by miRNAs has also been demonstrated [110,111]. Overall, these data indicate

that abrogated expression and/or function of VDR may be common in certain subsets of cells within individual tumors that have sustained specific molecular genetic alterations. Clones that escape anticancer VDR signaling may eventually acquire sufficient additional properties leading to malignant progression.

In addition to genetic alterations and effects of oncogenes, VDR abundance in tumor cells may be affected by many physiological agents, including 1,25(OH)<sub>2</sub>D itself, estrogens, retinoids, and growth factors. Thus, cell sensitivity to 1,25(OH)<sub>2</sub>D may also reflect the activity of other hormone signaling pathways through their impact on VDR expression. In breast cancer, the regulation of VDR expression and activity by estrogens is likely to be clinically significant. Tumors that are positive for ER and PR express higher levels of VDR than ER-negative cells [102,112] and in vitro studies have demonstrated that estrogens, antiestrogens, and phytoestrogens regulate VDR in ER-positive breast cancer cells [113,114]. The degree to which estrogen status and commonly utilized synthetic or natural estrogens impact VDR expression in tumors is unclear and additional studies are necessary to assess the clinical relevance of these in vitro findings.

With respect to ligand availability, factors that enhance mammary cell catabolism of 1,25(OH)<sub>2</sub>D such as amplification of the *CYP24A1* gene [115] can also contribute to abrogation of VDR signaling. Analysis of TCGA datasets [101] confirms that a subset of human breast cancers (10%–13%) exhibit alterations in *CYP24A1*, with the most frequent changes being amplifications leading to upregulation at the mRNA level [104]. These data are consistent with the analysis of tumor samples which demonstrated amplification and/or higher protein expression of *CYP24A1* in breast tumors compared to adjacent normal tissue [90,94,115]. It is also worth noting that *CYP24A1* splice variants have been found in breast cancer cell lines [116], suggesting that distinct forms of the enzyme with altered properties may be expressed in tumors. *CYP24A1* alterations were found in all tumor subtypes, although amplifications were somewhat more frequent in Luminal B and HER2 tumors while increased *CYP24A1* mRNA was more common in Basal and Claudin-low tumors. Elevated *CYP24A1* expression correlated with reduced regression-free survival in the METABRIC dataset of >1900 breast cancers [104]. However, it is difficult to determine the extent to which increased *CYP24A1* expression contributes to disease progression since the amplified genomic region at 20q13 contains more than 300 distinct genes in addition to *CYP24A1* [104].

Given that normal mammary cells utilize 25(OH)D as substrate for local tissue generation of 1,25(OH)<sub>2</sub>D,

imbalanced expression of *CYP27B1* relative to *CYP24A1* could also theoretically contribute to the escape of tumor cells from anticancer VDR signaling. Oncogenic transformation of normal mammary epithelial cells was associated with reductions in *CYP27B1* expression and activity that were of sufficient magnitude to reduce cellular sensitivity to 25(OH)D approximately 100-fold [98]. However, clinical data on *CYP27B1* expression in breast cancer is inconsistent [90,94,117–119], and less than 2% of breast cancers annotated in TCGA datasets exhibit genomic alterations in *CYP27B1* [101]. In the METABRIC dataset cited above, *CYP27B1* alterations were almost exclusively up-regulations at the mRNA level [104]. Similar to *CYP24A1*, altered splice variants of *CYP27B1* have been detected in breast cancer cells [120,121] suggesting the possibility that forms of the enzyme with altered function could be expressed in breast tumors. Additional investigations are clearly needed to assess the clinical significance of *CYP24A1* and *CYP27B1* deregulation with respect to tumor progression.

## 4. Impact of vitamin D signaling in animal models of breast cancer

### 4.1 Overview of in vivo studies

Animal models of breast cancer have been extensively utilized to assess the effects of the vitamin D pathway on tumorigenesis. Early chemical carcinogenesis studies and trials with xenograft models formally established the efficacy of synthetic VDR agonists to prevent tumor development and reduce the growth of established tumors. In some cases, regression of existing tumors associated with apoptosis induction was reported. These data provided important proof of the principle that the antiproliferative and proapoptotic effects of 1,25(OH)<sub>2</sub>D that are consistently demonstrated in vitro could be achieved in vivo. Furthermore, synthetic analogs of 1,25(OH)<sub>2</sub>D were identified that elicited antitumor actions with minimal effects on calcemia (the most common and dangerous side effect of VDR-targeted therapies). A few animal studies also reported the efficacy of vitamin D analogs to reduce skeletal or other metastases and improve survival [122,123]. Please see Table 88.2 for a summary of newly published animal studies on the vitamin D pathway and breast cancer, some of which are highlighted below. Efforts have been focused on the use of knockout and transgenic models to assess mechanistic questions, the ability of dietary vitamin D to modulate tumor development and progression, and the promise of combination therapies.

### 4.2 Efficacy of vitamin D compounds to inhibit chemically induced carcinogenesis

In vivo, both high dietary vitamin D [105,124] and treatment with synthetic VDR agonists [105,125–129] inhibited the development of mammary tumors induced by chemical carcinogens such as MNU and DMBA. These tumors are typically estrogen-responsive and were shown to express VDR [130] suggesting the possibility that vitamin D compounds acted directly on tumor cells. The demonstration that VDR agonists including 1,25(OH)<sub>2</sub>D reduced the incidence of preneoplastic lesions induced by DMBA in mouse mammary gland organ cultures supports this suggestion [88,131]. Mechanistic studies in chemically-induced carcinogenesis models suggested that vitamin D exerted tumor-suppressive effects during the promotion and/or progression phases as opposed to the initiation phase [132].

### 4.3 Studies on VDR agonists, diet, and UVR in tumor graft models

Tumor grafts (both syngeneic and nonsyngeneic) have frequently been used to assess the in vivo effects of vitamin D signaling on breast tumorigenesis. Nonsyngeneic models include grafts of established cancer cells (usually human) into immune-deficient mice whereas syngeneic models involve grafting of murine cells into immune-competent host mice of identical genetic background. Numerous synthetic vitamin D analogs, including EB1089 and BXL0124, effectively inhibited the growth of ER+ (MCF-7) and ER– (MDA-231, MCF10DCIS.com, SUM159PT) tumors grafted in nude mice [123,128,133,134]. EB1089 also reduced the extent of skeletal metastases (total number of bone metastases, surface area of osteolytic lesions, and tumor burden within bone) and enhanced survival after intracardiac injection of MDA-MB-231 human breast cancer cells [122].

The absolute requirement for VDR in tumor responses to vitamin D-based therapies was first demonstrated in a study of EB1089-treated nude mice bearing xenografts of mammary tumor cells derived from wild-type or VDRKO mice [133]. Only tumors composed of VDR-positive cells from wild-type mice responded to EB1089 indicating that VDR in the mouse stroma or other tumor-infiltrating cells is not sufficient to mediate anticancer signaling in the context of a xenografted tumor. A novel aspect of this study was the demonstration that exposure of tumor bearing mice to UVR elevated serum 25D and reduced the growth rate of VDR-positive but not VDR-negative tumors [133]. Williams et al. [135] reported that shRNA-mediated

knockdown of *Vdr* in 168-FARN murine mammary tumor cells resulted in tumor grafts that grew faster and metastasized more readily than their *Vdr*-expressing counterparts. Importantly, these effects were reversed when *Vdr* was restored into *Vdr* knockdown cells. The effects of both VDR signaling and dietary vitamin D manipulation in this study were mechanistically linked to the regulation of the *Id1* oncogene. A suppressive role of VDR in metastatic spread was reported by Zhang et al. [96] who demonstrated that *Vdr* overexpression in 4T1 murine mammary tumor grafts suppressed lung colonization relative to that of control 4T1 grafts with low *Vdr* expression, and this effect was attributed to suppression of  $\beta$ -catenin by VDR. In MDA-MB-231 TNBC cells, VDR knockdown promoted epithelial-mesenchymal transition, migration, invasion, and skeletal colonization. Expression of vitamin D metabolic enzymes can also impact tumorigenesis. For example, allografts of TM40D mammary tumor cells grew more rapidly in *Cypb27b1* KO mice compared to wild-type mice, effects that were attributed to elevated oxidative stress, DNA damage, and senescence and were prevented by administration of 1,25(OH)<sub>2</sub>D but not 25(OH)D [80]. Consistent with these observations, shRNA-mediated inhibition of *CYP24A1* expression reduced the growth of TNBC xenografts through suppression of proliferation and angiogenesis in conjunction with activation of apoptosis and necrosis [136]. Collectively, this series of studies clearly demonstrated that VDR expression and availability of its ligand 1,25(OH)<sub>2</sub>D impact oncogenic signaling and tumor behavior in vivo.

Several studies have investigated whether dietary vitamin D manipulations alter the growth of breast xenografts. Swami et al. [137] demonstrated that increasing dietary vitamin D from 1000 IU/kg diet (rodent standard) to 5000 IU/kg diet significantly reduced the growth of established MCF-7 xenografts with a potency equivalent to that of treatment with 1,25(OH)<sub>2</sub>D [137]. This group also demonstrated that vitamin D signaling exerted inhibitory effects on aromatase gene expression and activity leading to reduction in estrogen-stimulated tumor growth. Supplemental dietary vitamin D also abrogated the tumor-promoting effects of obesity in a syngeneic graft model with Wnt1 cells [138]. Conversely, dietary vitamin D deficiency enhanced the growth of *Wnt1*-driven tumor grafts [135,139]. In a metastasis model in which either MCF-7 or MDA-MB-231-TxSA breast cancer cells were injected directly into the tibia of nude mice, vitamin D deficiency sufficient to elevate PTH and enhance bone turnover promoted the development of larger osteosclerotic lesions compared to those of vitamin D sufficient mice [140,141].

The possibility that vitamin D signaling affects anti-tumor immunity has been assessed in immune-competent models with murine allografts. Karkeni et al. [142] demonstrated that vitamin D supplementation promoted infiltration of CD8<sup>+</sup> T cells into E0771 allografts, decreased systemic inflammation, and reduced M1 macrophages in association with a reduction of tumor burden. Interestingly, the effects of vitamin D supplementation were abrogated by obesity. In a comprehensive series of studies that compared several allograft models, vitamin D supplementation had divergent effects on tumor growth, metastasis, blood flow, immune cell populations, systemic cytokines, and fibroblast phenotype [143–146]. These studies demonstrated that both tumor cell heterogeneity and host genetic background influenced the response of tumor-bearing mice to dietary vitamin D.

#### 4.4 Effect of dietary vitamin D and/or VDR agonists on transgenic models of breast cancer

The first demonstration that activation of vitamin D signaling could reduce tumorigenesis in a genetically engineered model of breast cancer was reported in 2005. This study utilized luteinizing hormone (LH) over-expressing mice, a model of chronic ovarian stimulation which leads to hormone-responsive mammary tumors with abundant VDR expression. Treatment with the low-calcemic vitamin D analog EB1089 decreased proliferation of mammary epithelial cells in preneoplastic glands and reduced the growth rate of a subset of tumors. Subsequent studies in the MMTV-NEU mouse model which mimics the HER2 subtype of human breast cancer demonstrated that the Gemini analog BXL0124 inhibited tumor growth and down-regulated oncogenic pathways driven by HER2 (such as ERK and AKT). Importantly, tumor growth inhibition was only observed when BXL0124 treatment was initiated prior to the development of palpable tumors suggesting that VDR signaling may become corrupted with tumor progression in this model [147,148].

Two recent studies evaluated the role of local generation of 1,25(OH)<sub>2</sub>D in transgenic mice that express the Polyoma Virus middle T antigen in the mammary gland (MMTV-PyMT mice). Tumors in this model are driven by the activation of numerous oncogenic pathways including MAPK, PI3K, and PLC- $\gamma$ . Tumor development was accelerated in MMTV-PyMT mice fed a low (25 IU/kg) vitamin D diet relative to those fed 1000 IU/kg vitamin D [149]. Conversely, systemic administration of 25(OH)D or 1,25(OH)<sub>2</sub>D delayed tumor appearance and decreased lung metastasis in this

model. Perfusion of mice with 25(OH)<sub>2</sub>D resulted in the accumulation of 1,25(OH)<sub>2</sub>D in tumors, supporting the idea that conversion of 25D to 1,25(OH)<sub>2</sub>D by tumor CYP27B1 occurred. In further support of this idea, the deletion of *Cyp27b1* in the mammary epithelium of MMTV-PyMT mice accelerated mammary tumorigenesis and up-regulated markers of cell proliferation, angiogenesis, cell cycle progression, and survival [150]. Oncogenic pathways including AKT, NF-κB, and STAT3 were increased in *Cyp27b1*-ablated tumors compared with nonablated controls.

#### 4.5 Effect of *Vdr* ablation on mammary carcinogenesis

In a follow-up to the rodent chemical carcinogenesis studies cited above, the effect of *Vdr* ablation on DMBA-induced mammary tumorigenesis was assessed. Zinser et al. [151] reported that VDRKO mice (maintained on the rescue diet to prevent hypocalcemia) exhibited an increased incidence of mammary gland hyperplasia and a higher percentage of hormone-independent tumors with squamous differentiation after treatment with DMBA than wild-type mice. In the transgenic MMTV-NEU mouse model of mammary cancer, mice heterozygous for *Vdr* exhibited shortened tumor latency and increased tumor incidence compared to wild-type mice [152]. Another study examined the effect of *Vdr* ablation in mice expressing the RON oncogene in the mammary epithelium (MMTV-RON mice), which develop mammary tumors associated with hyperactive β-catenin signaling. On the MMTV-RON background, mice homozygous or heterozygous for *Vdr* exhibited significantly longer times to palpable tumor formation compared to those with complete *Vdr* ablation [153]. Furthermore, *Vdr* deletion significantly increased the number of metastases in the lung and liver relative to that of mice homozygous or heterozygous for *Vdr*. The ability of VDR to suppress RON-mediated tumorigenesis was mechanistically linked to the induction of DKK-1 (a Wnt pathway inhibitor) and attenuation of β-catenin signaling by 1,25(OH)<sub>2</sub>D [153].

### 5. Genomic profiling of VDR agonists in breast cancer model systems

#### 5.1 Overview

Screening for molecular changes induced by 1,25(OH)<sub>2</sub>D or vitamin D analogs in various breast cancer model systems has identified a broad range of downstream VDR targets. Cell biology studies generally focus on a few targets to mechanistically assess their involvement in tumor responses to VDR agonists. In contrast,

genomic profiling typically identifies hundreds of vitamin D-regulated genes and allows for predictions of how these gene alterations may affect cellular pathways. While *CYP24A1* is commonly identified in microarray studies as the most highly up-regulated gene in 1,25(OH)<sub>2</sub>D-treated cells, other target genes vary greatly depending on the model system. Here we will focus on the few comprehensive genomic studies that have allowed for unbiased identification of vitamin D-responsive pathways in normal mammary cells and those derived from various types of breast cancer [74,154–159].

#### 5.2 1,25(OH)<sub>2</sub>D regulated genes and enriched pathways in nontumorigenic mammary epithelial cells

To identify potential mediators of vitamin D actions in cancer prevention, microarray profiling in nontransformed mammary epithelial cells (hTERT-HME1 cells) treated with 100 nM 1,25(OH)<sub>2</sub>D for 24 h was conducted [159]. It was previously shown that the biological responses of hTERT-HME1 cells to 1,25(OH)<sub>2</sub>D are highly similar to that of primary cultures of human breast epithelial cells indicating that the immortalization process per se does not affect VDR expression or function [89]. Treatment with 1,25(OH)<sub>2</sub>D significantly altered the expression of over 450 entities (65% up-regulated/35% down-regulated) in hTERT-HME1 cells. The top up-regulated genes included *CYP24A1*, *CD14*, *ITGB3*, *SLC1A1*, *DHRS9* and *BMP6*, while the top down-regulated genes included *KDR*, *BIRC3*, *RGS2*, and *GLUL*. These differentially expressed genes were associated with the enrichment of 42 biological pathways including senescence and autophagy, cell cycle checkpoints, and TGFβ signaling. Enrichment of these pathways is consistent with reports that longer-term incubation of hTERT-HME1 cells with 100 nM 1,25(OH)<sub>2</sub>D induces growth inhibition [89] and that TGFβ inhibits mammary epithelial cell growth [160]. Additional tumor suppressive pathways enriched in this gene set included those related to oxidative stress, Nrf2 signaling, cell adhesion, immune responses, and cellular metabolism as well as pathways related to distinct differentiated phenotypes (adipogenesis, angiogenesis, osteogenesis, and osteoclastogenesis). A subset of putative VDR target genes (*ITGB3*, *GLUL*, *KDR*, *BIRC3*, *SLC1A1*, *CD14*, *BMP6*, *IL1RL1*, *IL33*) was validated as 1,25(OH)<sub>2</sub>D-responsive in two independently derived telomerase immortalized HME cell lines [159,161] and the effects of 1,25(OH)<sub>2</sub>D were consistent with the initial array data. Thus these genes appear to be bonafide VDR targets in nontransformed mammary epithelial cells. It is worth noting that regulation of these

genes in response to  $1,25(\text{OH})_2\text{D}$  was highly discordant in nontumorigenic MCF10A cells, which are commonly used as a model of “normal” mammary epithelial cells and thus would be expected to respond comparably to the telomerase immortalized HME cells. Only two down-regulated genes (*KDR* and *BIRC3*) were similarly altered by  $1,25(\text{OH})_2\text{D}$  in hTERT-HME1 and MCF10A cells. Others that were down (*GLUL*) or up (*ITGB3*, *SLC1A1*) regulated by  $1,25(\text{OH})_2\text{D}$  in the immortalized HME cells were unaffected in MCF10A cells [159,161]. These data suggest that MCF10A cells, despite their nontumorigenic phenotype, may not be an appropriate model for the assessment of  $1,25(\text{OH})_2\text{D}$  actions in normal breast epithelial cells. Examination of the effects of  $1,25(\text{OH})_2\text{D}$  on several breast cancer cell lines also demonstrated considerable diversity in the regulation of these candidate genes. The discordance in gene regulation between nontumorigenic and cancerous cells was not due to reduced VDR sensitivity as  $1,25(\text{OH})_2\text{D}$  comparably induced *CYP24A1* (700–900-fold) in the various cell lines. In addition, the ability of  $1,25(\text{OH})_2\text{D}$  to alter expression did not obviously correlate with the basal expression of genes in these cell lines.

### 5.3 Genomic profiling in breast cancer cell lines

In the first genomic profiling of vitamin D actions in breast cancer cells, Feldman's group compared gene expression in ER+ MCF-7 cells and ER– MDA-MB-231 cells treated with 100 nM  $1,25(\text{OH})_2\text{D}$  for 24 h [162]. Due to the limited nature of these first-generation arrays, which were comprised of 2000 cancer-related genes, direct comparisons with newer datasets from whole genome profiling are not appropriate, but comparisons between the two cell lines is of interest. The study found differential expression of 62 genes in MCF-7 cells (47 up/15 down) as compared to 20 genes in MDA-MB-231 cells (10 up/10 down), with only seven genes commonly altered in both cell lines. The larger number of  $1,25(\text{OH})_2\text{D}$  regulated genes in MCF-7 cells was consistent with higher *CYP24A1* induction in these cells (52-fold) compared to MDA-MB-231 cells (5.5-fold). Significantly regulated genes in MCF-7 cells treated with  $1,25(\text{OH})_2\text{D}$  included *RBL2*, *CTNNA1*, *RAD23B*, *NCOA4*, *BMP5* and *IFNG* (up) and *CEACAM1*, *CDH6*, *IL13*, *IL1R2* and *ESR* (down). Highly modulated genes in MDA-MB-231 cells included *CASP4*, *NF1B*, *ITGAV*, *TXNRD1* and *TGFB2* (up) and *ANGPT1*, four *MMPs* (12, 10, 7, 1) and *PRKD1* (down). Although pathway analysis was not conducted, many of the  $1,25(\text{OH})_2\text{D}$  regulated genes in MCF-7 cells were linked to growth factor signaling, cell cycle, apoptosis, and immune responses, whereas genes related to disease progression (i.e., invasion and

angiogenesis) were more highly regulated in MDA-MB-231 cells.

Another array study compared the effects of 12 h treatment with 1 nM RO3582 (a Gemini  $1,25(\text{OH})_2\text{D}$  analog) in a model of premalignant (MCF10AT1) and malignant (MCF10CA1a) disease [156]. Consistent with the results in MCF-7 versus MDA-MB-231 cells [162], the less malignant MCF10AT1 cells displayed more significant changes in gene expression than the invasive MCF10CA1a cells (391 vs. 156, respectively). Despite the differences in sensitivity, about 55% of the genes altered in MCF10AT1 cells were similarly altered in the MCF10CA1a cells. The similarity in response is likely due to the common genetic background of these two cell lines, as both are derivatives of the MCF10A cell line discussed above.

Simmons et al. [159] reported whole genome profiling of MCF-7 cells (a model of luminal breast cancer) treated for 24 h with 100 nM  $1,25(\text{OH})_2\text{D}$ . In this analysis, 249 entities were significantly altered by  $1,25(\text{OH})_2\text{D}$  (153 up-regulated/96 down-regulated). The top up-regulated genes included *CYP24A1*, *KLK6*, *TRPV6*, *CP*, and *MERTK*, while the top down-regulated genes included *PMP22*, *CTGF*, *CLDN1*, and *ILIR1*. Pathway analysis of this MCF-7 dataset indicated enrichment of genes in 31 pathways, eight of which (senescence and autophagy, TGF $\beta$  signaling, endochondral ossification, adipogenesis, nuclear receptors in lipid metabolism/toxicity, oncostatin M signaling, integrated pancreatic cancer pathway, and integrin-mediated cell adhesion) were common to those enriched in the nontumorigenic hTERT-HME1 cell gene set discussed above. Perhaps more relevant for the disease process were the high-scoring cancer-relevant pathways altered by  $1,25(\text{OH})_2\text{D}$  in MCF-7 cells but not in hTERT-HME1 cells which included Phase I metabolism, apoptosis modulation and signaling, estrogen/tamoxifen metabolism, and ATM signaling.

Another publicly available dataset was reported by Goeman et al. [163] who utilized RNA-Seq to generate a list of differentially expressed genes in SKBR3 cells (a model of HER2+ breast cancer with mutant p53) treated for 6 h with 100 nM  $1,25(\text{OH})_2\text{D}$ . Simmons et al. [159] compared this dataset with their data from  $1,25(\text{OH})_2\text{D}$ -treated hTERT-HME1 and MCF-7 cells and identified 17 genes that were altered by  $1,25(\text{OH})_2\text{D}$  in all three breast-derived cell lines, however only 11 of these genes were regulated in the same direction (9 up, 2 down). Additional comparisons identified 26 genes coregulated by  $1,25(\text{OH})_2\text{D}$  in the two cancer cell lines (SKBR3 and MCF-7 cells) and 20 genes coregulated by  $1,25(\text{OH})_2\text{D}$  in SKBR3 and hTERT-HME1 cells. The full lists of gene changes are available in the publication by Simmons et al. [159].

The role of VDR signaling in genomic responses to 1,25(OH)<sub>2</sub>D has been studied in a mouse mammary tumor model of TNBC [164]. Cells derived from DMBA-induced tumors generated in wild-type and VDRKO mice were analyzed 24 h after treatment with 100 nM 1,25(OH)<sub>2</sub>D. As expected, genomic profiling demonstrated that 1,25(OH)<sub>2</sub>D failed to alter gene expression in VDRKO cells whereas major changes were observed in cells derived from wild-type mice (WT cell line). This study also included three clonal lines of VDRKO cells engineered to stably express human VDR (KO<sup>hVDR</sup> cells) which conferred sensitivity to the growth inhibitory effects of 1,25(OH)<sub>2</sub>D. With a twofold cutoff, 117 transcripts in WT cells and 197 transcripts in KO<sup>hVDR</sup> clones were significantly altered by 1,25(OH)<sub>2</sub>D with 35 genes found to be commonly regulated in all VDR+ cell lines (the complete list of genes is included in the manuscript). In addition to *Cyp24a1*, seven genes were validated as 1,25(OH)<sub>2</sub>D responsive and VDR dependent in this system: *Cib2*, *Prep1*, *Enpp1*, *Plau*, *Hbegf*, *Postn*, and *Has2*. The last four of these, whose expression was markedly down-regulated by 1,25(OH)<sub>2</sub>D, are known to drive breast cancer invasion and metastasis. These data support a working model whereby 1,25(OH)<sub>2</sub>D coordinately suppresses multiple genes and pathways that are required for the survival and invasion of TNBC cells.

#### 5.4 Profiling of VDR-regulated gene expression in human breast cancers

Two approaches have been used to identify potential VDR targets in human breast cancers: exposure of patient-derived tumor explants to 1,25(OH)<sub>2</sub>D ex vivo, and interrogation of publicly accessible datasets. Genome profiling in freshly isolated breast tumor explants assesses whether the vitamin D pathway is functional in the complex multicellular tumor environment that exists in vivo. In the first study of this kind, tumor slices from postmenopausal patients with stage I, II, or III breast cancer were cultured with 0.5 nM or 100 nM 1,25(OH)<sub>2</sub>D for 24h [155]. At the lower dose of 0.5 nM, 10 genes were significantly altered: *CYP24A1*, *DPP4*, *CYP26B1*, *SPIN3*, *KCKN3*, *EFTUD1*, *TKTL1*, and *CA2* (up-regulated) and *FCGR2C* and *SAMSN1* (down-regulated). Of these, *CYP24A1* was induced over sevenfold and was validated in another set of tumor samples, clearly indicating activation of VDR signaling. At 100 nM 1,25(OH)<sub>2</sub>D, 30 genes (28 up/2 down) were significantly altered by 1,25(OH)<sub>2</sub>D. In addition to those regulated by 0.5 nM 1,25(OH)<sub>2</sub>D, genes up-regulated threefold or more after treatment with 100 nM 1,25(OH)<sub>2</sub>D included *IL1RL1*, *CILP*, *P115*, *TMEM37*,

and *SHE*. The two top-down-regulated genes (2-fold or more) were *P2RY1* and *BCOR*. This dataset is publicly available on the Gene Expression Omnibus website (accession #GSE27220). The significance of this study is that it demonstrated for the first time that 1,25(OH)<sub>2</sub>D could directly influence gene expression in patient-derived multicellular tumor tissue, confirming the functionality of the VDR in human breast cancer. Although patient-to-patient variability was considerable, a clear dose–response in gene expression to the two concentrations of 1,25(OH)<sub>2</sub>D was detected. To assess whether genes altered in tumor tissue by 1,25(OH)<sub>2</sub>D were also altered in cell lines, Simmons et al. [159] integrated the dataset of breast tumor explants exposed to 100 nM 1,25(OH)<sub>2</sub>D with those from the hTERT-HME1, MCF-7 and SKBR3 cell lines. This analysis identified four genes (*CYP24A1*, *CLMN*, *EFTUD1*, and *SERPINB1*) that were up-regulated by 1,25(OH)<sub>2</sub>D in the tumor explants and in all three breast-derived cell lines. A fifth gene, *IL1RL1*, was common to all four datasets but was down-regulated in SKBR3 cells and up-regulated in the other three model systems. There were no genes identified that were down-regulated by 1,25(OH)<sub>2</sub>D in all model systems.

In a similar ex vivo explant model, genomic responses to 1,25(OH)<sub>2</sub>D were compared in explants of breast tumors and normal adjacent tissue [157,158]. This analysis demonstrated >500 differentially expressed genes in breast cancer versus 127 in normal breast tissues. Pathway analysis revealed that 1,25(OH)<sub>2</sub>D down-regulated cellular metabolic pathways and enriched pathways involved with intercellular adhesion. Remarkably, the same four genes (*CYP24A1*, *CLMN*, *SERPINB1*, *EFTUD1*) identified as common VDR targets in the analysis by Simmons et al. [159] were the most highly induced genes in this second explant study. These four genes, as well as *KLK6*—a gene that was highly induced in both tumor explants and MCF-7 cells [159]—were confirmed as 1,25(OH)<sub>2</sub>D regulated in breast cancer cell lines and in a subset of human clinical samples from normal tissue and breast cancer.

Using an unbiased genomic profiling approach, Li et al. [105] interrogated four independent datasets comprising 581 breast cancer patients with ER+ breast tumors that had been treated with tamoxifen. Stratification by tumor VDR expression in these cohorts identified biological functions enriched in VDR “high” tumors including cell death and survival, cellular proliferation, and cancer. Additional analysis indicated repression of an autophagy gene signature in VDR “high” tumors, and repression of autophagy by 1,25(OH)<sub>2</sub>D was confirmed in ER+ breast cancer cell models in vitro.

## 5.5 Summary of genomic profiling data

Genomic effects of  $1,25(\text{OH})_2\text{D}$  in breast cancer model systems have clearly been established, and the initial integration of existing datasets has identified a common set of genes that may represent biomarkers of vitamin D action for future studies. While *CYP24A1* is commonly identified in microarray studies as the most highly up-regulated gene in  $1,25(\text{OH})_2\text{D}$  treated cells, other modulated genes vary greatly depending on the model system. While not wholly unexpected as transcriptional responses across cell types are in general highly diverse, determining the molecular basis for these differences is warranted. The distinct biological effects of  $1,25(\text{OH})_2\text{D}$  in different cell types could reflect differences in the expression of VDR, its RXR partners or transcriptional co-regulators as well as the underlying epigenetic states in specific genomic regions. A caveat to the current data is that most profiles were conducted after 24 h treatment, and thus will include both primary VDR target genes and downstream effectors (i.e., secondary targets). Similarly, genes differentially expressed in tumors with high versus low VDR expression would represent multiple downstream pathways potentially regulated by vitamin D signaling. It is anticipated that alterations in these downstream targets would be more variable in different model systems. In addition, an adaptation of cells to culture, the use of long-established cell lines, and the presence of cancer-associated genomic alterations likely contribute to this diversity. However, despite the potential artifacts of cell and tissue culture model systems, it is worth noting that several of the genes identified as  $1,25(\text{OH})_2\text{D}$ -modulated in nontumorigenic mammary epithelial cells [159], including *CD14*, *CD97*, *THBD*, *NINJ1*, *CAMP*, and *IL8*, have been identified as direct VDR targets by ChIP-seq and were altered in peripheral blood mononuclear cells by oral vitamin D supplementation, but only in a subset of trial participants [165]. This supports the feasibility of identifying biomarkers of vitamin D exposure through cell culture studies but also confirms the heterogeneity of individual responses. Continued integration of the datasets reported here with additional genomic profiles and ChIP-Seq data will assist in identifying more comprehensive common and tissue/cell-specific signatures of  $1,25(\text{OH})_2\text{D}$ -VDR signaling. The continued use of complex models such as tumor explants for vitamin D studies is desirable given the expression of VDR in most cell types and the critical interactions between tumor cells and their stromal microenvironment. Furthermore, targeted analysis of vitamin D pathway expression in large publicly available datasets to address specific hypotheses or evaluate specific patient populations remains worthwhile.

## 6. Mechanistic insight into vitamin D actions in breast cancer

### 6.1 Overview

Given the large number of genes and pathways regulated by  $1,25(\text{OH})_2\text{D}$  in breast cells, it is not surprising that vitamin D inhibits cancer development and progression via multiple mechanisms. The diverse mechanisms by which vitamin D signaling alters cell and tumor behavior have been reviewed [104,143,166,167] and are summarized in Table 88.3. This section will provide a brief summary of existing data while highlighting newly recognized effects of  $1,25(\text{OH})_2\text{D}$  on cellular metabolism and cancer stem cells.

Both  $25(\text{OH})\text{D}$  and  $1\alpha,25(\text{OH})_2\text{D}$  exert profound effects on nontumorigenic VDR+ mammary epithelial cells including regulation of basal and hormone-stimulated proliferation, induction of differentiation biomarkers such as E-cadherin, regulation of apoptosis and autophagy, protection against oxidative stress and inhibition of chemical carcinogenesis [72,82,88,89,98,185]. Other potential mechanisms of vitamin D action include reduction in DNA damage (possibly via up-regulation of p53 signaling), inhibition of angiogenesis, and increased antiinflammatory signaling although these effects have primarily been demonstrated in tissues or cell types other than mammary gland [185–198]. The possibility that  $1,25(\text{OH})_2\text{D}$  modulates cross-talk between mammary epithelial cells and immune responses is supported by the identification of numerous cytokines and their receptors as VDR targets including *CD14*, *IL1RL1*, and *IL1 $\alpha$*  [159,199,200]. In established breast cancer cells,  $1,25(\text{OH})_2\text{D}$  modulates key cell cycle regulators to induce cell cycle arrest, trigger differentiation, and/or activate cell death via apoptosis or autophagy. As discussed above, cells derived from VDRKO mice have been used to definitely establish that VDR is required for the antiproliferative and pro-apoptotic effects of  $1,25(\text{OH})_2\text{D}$  in vitro and in vivo [133,201,202].

Interactions between VDR and estrogen signaling contribute to the effects of  $1,25(\text{OH})_2\text{D}$  in hormone-dependent breast cancer cells. The  $1,25(\text{OH})_2\text{D}$ -VDR complex directly represses ER via two negative vitamin D response elements and also represses estrogen synthesis via inhibition of aromatase transcription [203,204]. These combined actions lead to the disruption of estrogen-stimulated proliferation and survival pathways in vitro and in an in vivo model of hormone-responsive breast cancer associated with obesity [138]. Given that the majority of human breast cancers are hormone-dependent and that ER+ tumors have the highest VDR expression, optimizing vitamin D status to abrogate estrogen-driven pathways in breast tumors

could translate into the prevention or delay of tumorigenesis for large numbers of women. This concept is supported by the proven action of the antiestrogen tamoxifen which was shown in RCTs to reduce breast cancer development by approximately 50% in women at high risk of breast cancer [205]. Related to this, high tumor VDR expression was associated with longer recurrence-free survival in tamoxifen-treated breast cancer patients [105].

Although estrogen-independent breast cancer cells, representative of late-stage disease, are in general less sensitive to 1,25(OH)<sub>2</sub>D-mediated cell cycle regulation, effects on genomic stability, invasion, and metastatic potential have been demonstrated. For instance, 1,25(OH)<sub>2</sub>D stabilized the 53BP1 protein and selectively eliminated invasive breast cancer cells expressing mutant *BRCA1* [206]. 1,25(OH)<sub>2</sub>D consistently inhibits invasion as measured in Boyden chambers [123] and metastasis as measured in 3D culture models [180]. Potential mechanisms by which vitamin D signaling reduces invasion and metastasis include suppression of extracellular proteases (MMP-9, urokinase-type plasminogen activator, tissue-type plasminogen activator), protease inhibitors, and adhesion molecules [164,207]. 1,25(OH)<sub>2</sub>D also inhibits the synthesis and secretion of hyaluronic acid, a major component of the tumor microenvironment that drives progression [168,208].

Many recent studies have explored whether vitamin D signaling exerts additive or synergistic effects with other agents. Thakkar et al. [209] characterized 15 breast cancer cell lines and reported that approximately two-thirds of TNBC cell lines co-express AR and VDR and that simultaneously targeting these two receptors resulted in additive antiproliferative effects. Other combination therapies that have recently been shown to exert additive or synergistic effects with VDR agonists in breast cancer cells include metformin [210], cox-2 inhibitors [211], the EGFR inhibitor gefitinib [212], ionizing radiation [213], the multikinase inhibitor dovitinib [214] and many others. A detailed discussion of these many studies is beyond the scope of this chapter, and a recent review is available on this topic [215].

## 6.2 Emerging role of vitamin D pathway in cancer cell metabolism

A role for vitamin D in the regulation of energy and amino acid metabolism of both normal and tumor cells has been suggested based on genomic and metabolomic analyses [157,159,216]. This role is of considerable interest given the adaptive changes in energy metabolism required for rapid proliferation and macromolecule synthesis in cancer cells [217,218]. The “metabolic switch” originally proposed by Warburg [217] is now known to

be promoted by oncogenes such as *MYC* and *RAS* and prevented by tumor suppressors such as *TP53* [219–225]. Agents that block *MYC* activation and/or elicit p53-like actions to disrupt the metabolic adaptations in glucose and amino acid metabolism and abrogate the metabolic switch would theoretically have therapeutic potential.

In this context, 1,25(OH)<sub>2</sub>D has been shown to regulate glucose and amino acid metabolism in association with growth inhibition of nontumorigenic mammary epithelial cells [182,216,226]. The glutamate transporter EAAT3 (encoded by *SLC1A1*) and enzyme glutamine synthetase (GS, encoded by *GLUL*) were identified and confirmed as 1,25(OH)<sub>2</sub>D targets in hTERT-HME1 cells [159,161,182]. 1,25(OH)<sub>2</sub>D increased *SLC1A1* mRNA (>10-fold) and decreased *GLUL* mRNA (>4-fold) with predicted effects on expression of the cognate proteins EAAT3 and GS. In 1,25(OH)<sub>2</sub>D treated cells, changes in expression of *SLC1A1* and several other glutamate transporters correlated with altered cellular glutamate handling, accumulation of glutathione, and changes in respiratory capacity. Suppression of GS by 1,25(OH)<sub>2</sub>D is particularly intriguing as this enzyme is required for the conversion of glutamate to glutamine, a nitrogen donor essential for production of purine and pyrimidine nucleotides during cell proliferation [218]. Indeed, 1,25(OH)<sub>2</sub>D treated cells exhibited reduced mitochondrial respiration of glutamine and failed to adapt to glutamine deprivation. Furthermore, exogenous glutamine partially rescued growth inhibition by 1,25(OH)<sub>2</sub>D. These findings demonstrating regulation of *SLC1A1* and *GLUL* by 1,25(OH)<sub>2</sub>D are intriguing because: (a) glutamate uptake and glutamate transporters are enhanced during differentiation and deregulated in cancer cells; (b) *Slc1a1* null mice exhibit GSH deficiency and high oxidative stress and (c) GS enzymatic activity is necessary for adaption of mammary cells to glutamine depletion [227–230]. Furthermore, data on The Human Protein Atlas indicate that *SLC1A1* is reduced and GS is increased in human breast cancers relative to normal tissue. These studies support the concept that regulation of *SLC1A1* and *GLUL* by 1,25(OH)<sub>2</sub>D may synergize with p53 to alter metabolic flux, prevent the metabolic switch and induce quiescence in normal mammary epithelial cells.

Consistent with the regulation of amino acid transporters by 1,25(OH)<sub>2</sub>D in hTERT-HME1 cells, Zhou et al. [226] reported that 1,25(OH)<sub>2</sub>D repressed the *SLC1A5* glutamine transporter in RAS-transformed MCF10A (MCF10A-ras) cells and identified a negative VDRE site in the proximal promoter of this gene. *SLC1A5* encodes a major plasma membrane glutamine transporter and its down-regulation by 1,25(OH)<sub>2</sub>D was associated with reduced intracellular glutamine and glutamate concentrations. This group also

compared the regulation of cellular glucose metabolism by  $1,25(\text{OH})_2\text{D}$  in MCF10A-ras cells and the premalignant MCF10A cells from which they were derived [216]. In this model,  $1,25(\text{OH})_2\text{D}$  reduced the flux of glucose through glycolysis in both MCF10A and MCF10A-ras cells, with more pronounced effects in the transformed cells.  $1,25(\text{OH})_2\text{D}$  also reduced the flux of glucose to acetyl-coA and oxaloacetate in both cell lines, suggesting a reduction in TCA cycle activity. The predicted consequences of the  $1,25(\text{OH})_2\text{D}$  induced changes reported in this series of studies would be limited availability of TCA-derived precursors for macromolecule synthesis coincident with a reduction in proliferation.

Comprehensive comparison of luminal (MCF-7, T47D) and TNBC (MDA-MB-231, MDA-MB-468, HCC-1143) cells revealed that  $1,25(\text{OH})_2\text{D}$  affects metabolism in a cell-type dependent fashion [183]. In luminal cells,  $1,25(\text{OH})_2\text{D}$  enhanced the acidification rate (indicative of glycolysis) and induced serine accumulation, whereas in TNBC cells the main effect was to reduce mitochondrial respiration. In all breast cancer cell lines,  $1,25(\text{OH})_2\text{D}$  induced GAPDH and AMPK signaling. Despite the potential pro-survival impact of these actions,  $1,25(\text{OH})_2\text{D}$  sensitized cells to chemotherapeutic agents including 5-fluoruracil. Continued exploration into the actions of  $1,25(\text{OH})_2\text{D}$  on glucose, glutamate, and glutamine metabolism is warranted to fully determine its role in the regulation of these critical pathways during breast cancer onset and progression.

### 6.3 Regulation of breast cancer stem cell populations by $1,25(\text{OH})_2\text{D}$

The existence of cancer stem cells (CSCs) in human and rodent breast cancers is widely supported by clinical and experimental data [231]. The CSC theory proposes that breast cancers arise from a minor subpopulation of transformed breast progenitor cells which are necessary and sufficient for the initiation and maintenance of tumors. CSCs can be identified by surface markers ( $\text{CD44}^{\text{HI}}/\text{CD24}^{\text{NEG/LOW}}$  for human;  $\text{CD49f}^{\text{HI}}/\text{EpCam}^{\text{LOW}}$  for mouse) and/or activity of aldehyde dehydrogenase 1 (ALDH1+) and can be propagated in vitro as nonadherent spheres ("mammospheres"). Verification of the stemness of CSCs and their frequency is through limiting dilution assays in which cells are injected into host mice at increasing doses and the percentage of CSCs within the original cell population is calculated based on tumor incidence. Pathways linked to survival of CSCs include Wnt, Notch, and Sonic Hedgehog, all of which play a role in breast cancer progression. With respect to cancer treatment, it is well-accepted that CSCs display remarkable resistance to conventional therapies including radiation

and chemotherapeutics. It is anticipated that nontraditional therapies able to bypass the drug resistance of CSCs leading to their selective elimination will constitute new and highly effective strategies for the treatment of human cancers.

In one of the first studies to address the impact of vitamin D signaling on CSCs, Pervin et al. [232] demonstrated significantly reduced levels of VDR protein in mammospheres isolated from SKBR3, MCF-7, and HME-Ras cells compared to cells grown on plastic. The low expression of VDR in mammospheres precluded significant effects of  $1,25(\text{OH})_2\text{D}$  and  $25(\text{OH})\text{D}$  on gene expression. SKBR3 cells sorted for ALDH+ had higher expression of CD44 and lower expression of VDR than ALDH- populations, suggesting an inverse correlation between stemness and VDR. In SKBR3 cells, overexpression of VDR reduced, whereas knockdown of VDR enhanced, mammosphere number. The importance of this study was that it demonstrated a functional role for VDR in mammospheres which were shown to be enriched in cells positive for stem cell markers CD44 and ALDH. Further follow-up on the expression and regulation of VDR in the stem cell models used in this study is warranted.

In another study of human breast cancer cell lines, Thakkar et al. [209] examined whether  $1,25(\text{OH})_2\text{D}$  altered differentiation state, CSC marker expression, or tumorsphere forming efficiency of TNBC lines MFM-223 and CAL-148. In both lines,  $1,25(\text{OH})_2\text{D}$  inhibited tumorsphere formation, decreased the percentage of ALDH+ cells, and reduced CSC-associated markers including CD44. Interestingly, both of these cell lines have high expression of AR and combination therapy with AR and VDR agonists had additive effects on decreasing the CSC population and stemness markers including CD49f, SOX2, OCT4, Musashi, and Notch.

The effects of  $1,25(\text{OH})_2\text{D}$  and its Gemini analog BXL0124 on stem cell markers were studied in MCF10DCIS.com cells, which constitute a model of early stage basal-like breast cancer. MCF10DCIS.com cells are enriched in cells with high CD44 expression and form DCIS-like lesions when xenografted into immunodeficient mice. In vivo, BXL0124 reduced the growth of MCF10DCIS grafts and decreased tumor expression of both CD44s (standard form of CD44) and the variant CD44 forms which are often expressed in tumors (CD44v). Both  $1,25(\text{OH})_2\text{D}$  and BXL0124 strongly repressed CD44 proteins in vitro in a VDR and p53-dependent manner. Follow-up studies with this model [233] demonstrated that both vitamin D compounds reduced the  $\text{CD44}^{\text{HI}}/\text{CD24}^{\text{NEG/LOW}}$  population, decreased mammosphere forming efficiency, and repressed stemness and pluripotency markers including CD44, CD49f, c-Notch1, pNFkB, OCT4, and KLF-4. Mechanistically, the  $\text{CD44}^{\text{HI}}/\text{CD24}^{\text{NEG/LOW}}$  population

was found to be enriched in Notch activity and the amount of active Notch receptor was decreased by BXL0124, leading to reduction of downstream mediators including MYC. These effects were linked to the induction of HES-1 (an inhibitor of Notch1 signaling) by BXL0124 [234], supporting a model whereby BXL0124 suppresses the CD44<sup>HI</sup>/CD24<sup>NEG/LOW</sup> population of CSCs by HES1-mediated inhibition of Notch signaling.

Recent comprehensive genomic analysis of 1,25(OH)<sub>2</sub>D treated tumorspheres [177] reported 439 genes with >4-fold positive change and 703 genes with >4-fold negative change in normalized RNA expression compared to control tumorspheres. Both 1,25(OH)<sub>2</sub>D and BXL0124 down-regulated genes involved in the maintenance of breast cancer stem-like cells (e.g., *GDF15*), epithelial-mesenchymal transition, invasion and metastasis (e.g., *LCN2*, *S100A4*) and chemoresistance (e.g., *NGFR*, *PPP1R1B*, *AGR2*) while up-regulating genes associated with a basal-like phenotype (e.g., *KRT6A*, *KRT5*) and negative regulators of breast tumorigenesis (e.g., *EMP1*). Through comparison of their RNA-Seq data with published databases of human mammary gland and breast cancer cell lines, the group reported *TP63*, *CYP24A1*, *CD14*, *TRPV6*, *STAT4*, and *FABP6* as genes commonly regulated by 1,25(OH)<sub>2</sub>D and BXL0124. In particular, the p63 protein (an inducer of myoepithelial differentiation whose loss promotes migration, invasion, and distant metastasis) was validated as a VDR target in tumorspheres. Collectively, these data support the concept that vitamin D signaling prevents DCIS progression to invasive ductal carcinoma by inducing myoepithelial differentiation of the cancer stem-like cells. This concept is consistent with the reduced incidence of human DCIS with vitamin D supplementation as noted earlier [21,49].

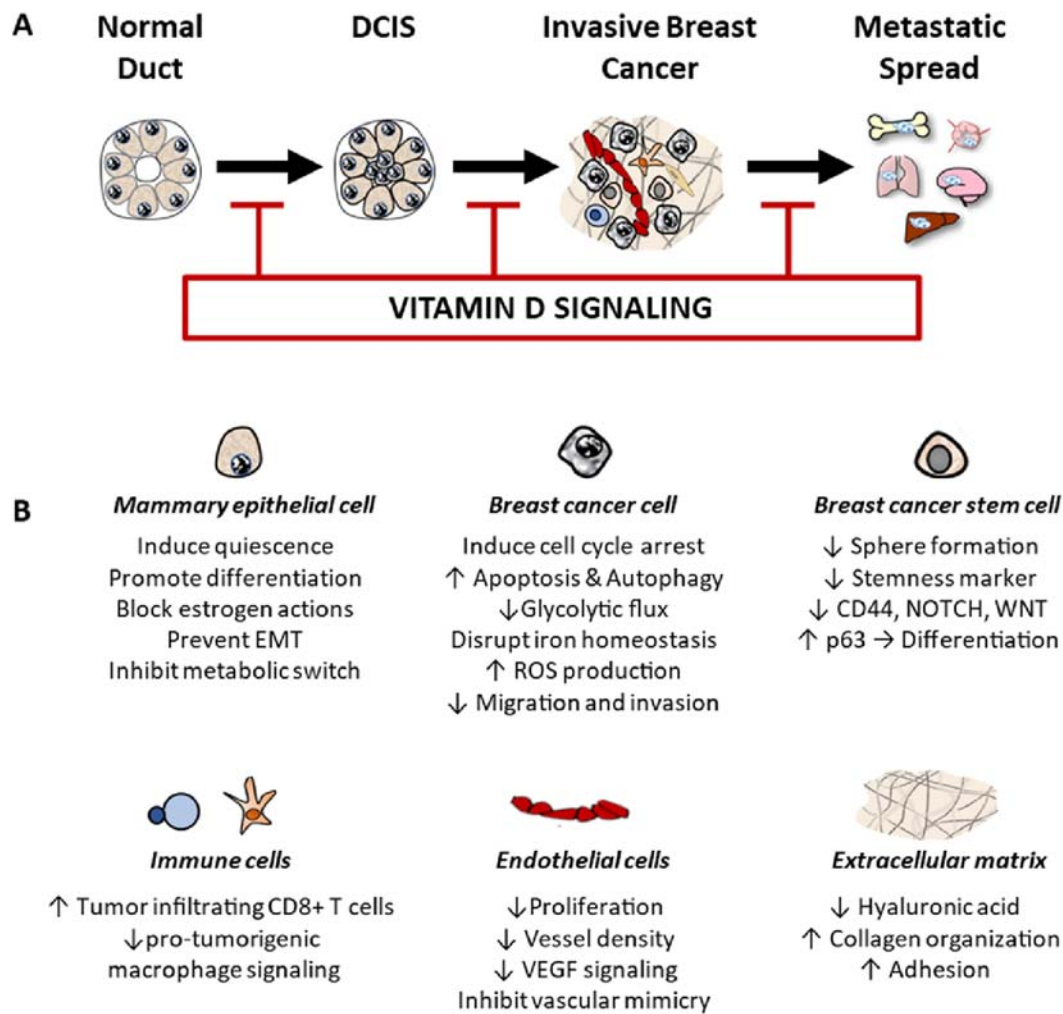

Similar inhibitory effects of 1,25(OH)<sub>2</sub>D on stem cell populations have been demonstrated in a *Wnt1*-driven murine mammary tumor model [139]. The authors first confirmed VDR pathway function in CSCs (CD49f<sup>HI</sup>/EpCam<sup>LOW</sup>) sorted from *Wnt1* tumorgrafts. Secondly, they demonstrated that 1,25(OH)<sub>2</sub>D at concentrations as low as 0.1 nM inhibited spheroid formation in primary culture and self-renewal in secondary passages. Most importantly, in vivo limiting dilution assays demonstrated a significant reduction in the frequency of CSCs in *Wnt1* cultures pre-treated with 1 nM 1,25(OH)<sub>2</sub>D. Gene expression assays on CSCs showed that 1,25(OH)<sub>2</sub>D reduced the expression of multiple WNT pathway genes including *Lef1*, *Axin2*, and *Ccnd*

and that forced expression of  $\beta$ -catenin abrogated the effects of 1,25(OH)<sub>2</sub>D on spheroid formation. These data extend the known targets of 1,25(OH)<sub>2</sub>D in CSCs to the WNT pathway, another critical driver of stemness and pluripotency.

In summary, these studies highlight the existence of a functional vitamin D pathway in CSCs which acts to robustly alter gene expression and inhibit stem cell function. While the clinical relevance of these observations remains to be seen, the work adds new insight into the actions of vitamin D in breast cancer and provides fertile ground for additional research. It is worth noting that the surface markers used to identify CSCs also function to mediate cell-cell interactions and activate survival pathways. In particular, CD44 is a cell surface glycoprotein that drives STAT3 survival signaling when activated by its ligand hyaluronic acid, the accumulation of which has consistently been associated with poor prognosis in breast cancer [235]. The hyaluronic acid pathway is also targeted by VDR in aggressive breast cancer cells [164], as 1,25(OH)<sub>2</sub>D markedly suppresses hyaluronan synthase-2 (HAS2) expression and decreases hyaluronic acid secretion. These effects of 1,25(OH)<sub>2</sub>D would be expected to further compromise CSC viability via the interruption of CD44-STAT3 survival signaling.

#### 6.4 Vitamin D pathway in tumor-infiltrating cells and extracellular matrix

In addition to the cancerous cells, many nonepithelial cell types accumulate in tumors including stromal fibroblasts, adipocytes, immune cells, and vascular endothelial cells. Increasing evidence suggests that the nonepithelial cells, which together with the extracellular matrix make up the tumor microenvironment, contribute to disease progression. It is worth noting that most of these cell types express VDR, creating a complex network of interacting cells that respond to 1,25(OH)<sub>2</sub>D (Fig. 88.2). With respect to breast cancer, VDR signaling has been shown to block pro-tumorigenic signaling from tumor-associated macrophages [96], inhibit endothelial cell proliferation and angiogenesis [214,236,237], alter extracellular matrix composition and components including collagen and hyaluronic acid [78,168,238], alter cytokine secretion from adipocytes [79] and increase the infiltration and activity of antitumor lymphocytes [142]. For general discussion of vitamin D and the tumor microenvironment, please see Wu et al. [239].

**FIGURE 88.2** Summary of vitamin D actions during breast cancer development and progression.

## 7. Conclusion

Despite significant progress in understanding the relationships between vitamin D and breast cancer, many issues remain unresolved. Much of the work conducted in cell systems or animal models are consistent, but epidemiological data remains mixed and clinical studies are limited. As discussed in this chapter, population studies largely support the concept that high serum levels of 25(OH)D are associated with lower risk of initial disease development and may retard progression. However, questions remain regarding mechanisms, tissue specificity, and optimal intake/blood concentration of vitamin D for potential benefits on cancer. Tissue uptake and cellular metabolism of vitamin D metabolites in vivo are likely to be highly relevant to cancer biology, yet few studies have successfully measured these parameters. With respect to breast cancer in particular, the microenvironment surrounding the epithelial cells at risk for carcinogenesis clearly contributes to risk,

and important functions of the VDR in adipocytes, stromal cells, immune cells, and vascular networks have been identified. Given the strong association of breast cancer and obesity, a renewed focus on vitamin D storage, metabolism, and actions in breast adipose tissue is warranted. With the emerging promise of immune therapies for solid cancers, efforts to dissect VDR actions with respect to immune surveillance in the context of breast cancer are also of high interest.

Further mechanistic insight into potential interaction between systemic vitamin D status and other known breast cancer risk factors including genetic (*BRCA1*, *BRCA2*, *ATM*), endocrine (estrogen, progesterone), and environmental (radiation, carcinogens) modulators is also needed. Genomic profiling has characterized many 1,25(OH)<sub>2</sub>D responsive targets in normal mammary cells and in breast cancers providing valuable insight into the molecular actions of 1,25(OH)<sub>2</sub>D and the VDR in regulation of cell cycle, apoptosis, and differentiation as well as regulation of tumor metabolism and

inhibition of cancer stem cells. As noted above, the role of VDR in individual cell types (i.e., epithelial, adipose, fibroblast, endothelial, immune) of normal and tumor tissues remains to be clarified. Furthermore, there has been limited attention directed at understanding how VDR integrates signaling between these diverse cell types and what soluble signals and paracrine pathways may be regulated by  $1,25(\text{OH})_2\text{D}$  in the tissue and tumor microenvironment. Finally, the possible interactions of VDR with other nuclear receptors (such as AR, ER, PGR, and RXRs) and their ligands in control of mammary cell fate/carcinogenesis are worthy of additional study. Comprehensive genomic, metabolomics, and proteomic profiling approaches combined with mechanistic studies remain highly valuable for the identification of relevant biomarkers of tissue vitamin D action that are needed to guide translational investigations such as supplementation trials.

## 8. Summary points

- VDR and the vitamin D metabolic enzymes CYP27B1 and CYP24A1 are expressed in the normal mammary gland and in the majority of human breast tumors.  $1,25(\text{OH})_2\text{D}$  and other VDR agonists exert tumor suppressive effects in breast cancer model systems both in vitro and in vivo. These effects are mediated via profound changes in the expression of genes associated with tumor-suppressive pathways.
- Population studies have demonstrated associations between vitamin D status (as measured by serum  $25(\text{OH})\text{D}$ ) and breast cancer risk and outcome. The association of higher vitamin D status with delayed recurrence and improved survival is convincing.
- In supplementation trials, vitamin D reduced the development of DCIS, a preneoplastic lesion, and was associated with a reduced risk of advanced/metastatic cancers.
- Vitamin D deficiency is common in breast cancer patients, particularly those with aggressive disease. Correction of vitamin D deficiency has the potential to improve outcomes in women living with breast cancer.

## Vitamin D and colorectal cancer

Gemma Ferrer-Mayorga, Alberto Muñoz and José Manuel González-Sancho

Instituto de Investigaciones Biomédicas “Alberto Sols”, Consejo Superior de Investigaciones Científicas, Universidad Autónoma de Madrid, Madrid, Spain

### OBJECTIVES

- Present the effects of  $1,25(\text{OH})_2\text{D}_3$  on cultured colon carcinoma cells, including the multifaceted antagonism of the Wnt/ $\beta$ -catenin signaling pathway.
- Present the effects of  $1,25(\text{OH})_2\text{D}_3$  on CRC patient-derived stromal tumor fibroblasts and colorectal organoids.
- Present and discuss the indirect actions of  $1,25(\text{OH})_2\text{D}_3$  that may affect CRC by modulating angiogenesis, immune response, detoxification, and microbiome.
- Review the literature on the effects of vitamin D,  $1,25(\text{OH})_2\text{D}_3$  or analogs in animal models of CRC.
- Discuss the discrepancy between the results of observational and experimental studies supporting a protective action of vitamin D against CRC and the unclear data from human intervention studies.

mutations by the genetic background, environment (mainly lifestyle factors and diet), ontogeny, and anatomy. Thus, there are differences in the mutational landscape and the clinical development, management, and response to therapies for right/ascending colon, left/descending colon, and rectal tumors. Sporadic CRC was for long considered a disease mostly diagnosed in the fifth or sixth decade of life or later; however, its incidence is increasing in people before age of 50 (early-onset CRC or EOCRC) while decreasing in the older population [1]. EOCRC shows specific genetic, epigenetic, and clinical features [2,3]. CRC heterogeneity is multifaceted: its incidence is higher among men, but women have a higher incidence of right-sided CRC, while EOCRC mortality is higher for men versus women and its incidence is higher among people of color versus white people particularly in right-sided colon tumors [4]. Two additional factors that modify the risk of CRC are intestinal microbiota and chronic inflammation, as shown by the increased risk of CRC in patients with inflammatory bowel disease (IBD: ulcerative colitis (UC) and Crohn's disease (CD)) [5,6].

### 1. Introduction

#### 1.1 Colorectal cancer

Colon/colorectal cancer (CRC) is a group of diseases that result from the malignant transformation of the epithelium lining the external surface of the large intestine. CRC is one of the most frequent neoplasia and a leading cause of death worldwide. CRC is heterogeneous in relation to age, location, alterations, sex, and race, which probably reflects the modulation of acquired

#### 1.2 Genetics and subtypes of colorectal cancer

CRC is the best characterized solid neoplasia in terms of genetic alterations. The malignant transformation of the intestinal epithelial cells occurs because of mutations and epigenetic modifications that are thought to progressively accumulate over 10–20 years. Due to this estimated long period of development, CRC represents an excellent model to interrogate the potential interactions between genetic alterations and environmental modifiable risk factors affecting cell epigenetics and thus,

gene expression and phenotype, identified as contributing to the disease.

In 1990, Fearon and Vogelstein proposed the first genetic model for CRC based on the accumulation of alterations in tumor suppressor genes (*adenomatous polyposis coli* or *APC*, *TP53*) and oncogenes (*KRAS*), known today as the suppressor pathway that leads to chromosomal instability and most (nonhypermuted) CRC cases [7]. Later, a second, alternative pathway, the mutator pathway, was proposed that affects a low proportion of cases (5%–10%), implies the loss or mutation of genes (*MSH2*, *MLH1*, *MSH6*, *PMS2*) that are involved in the repair of DNA replication errors or a 3' deletion in the *EPCAM* gene that causes the epigenetic silencing of *MSH2*. This mutator pathway is responsible for the microsatellite instability (MSI) or replication error phenotype causing the progressive accumulation of thousands of small mutations (DNA instability) characteristic of Lynch syndrome/hereditary nonpolyposis colon cancer (HNPCC) [8]. MSI also appears in sporadic CRC as a result of gene mutation or silencing (*MLH1*) in adult life, globally representing 15%–20% of total CRC. Another cause of hypermutated CRC is the alteration of *POLE* or *POLD1* genes encoding DNA polymerases involved in DNA base substitution. For an update on CRC genetics (germline and somatic mutations, epigenetic silencing, familial and sporadic, polyposis and nonpolyposis syndromes, and EOCRC diagnosed at young age), we recommend some reviews [9,10].

In addition to these stepwise models, a “Big Bang” model of single genomic catastrophe event and a “Cancer Punctuated Equilibrium” model of synchronous multiple mutagenesis episodes alternating with stable periods (stasis) have also been proposed as promoting CRC progression [11,12]. The majority of CRC cases are sporadic; only a minor (5%–10%) proportion of CRC is hereditary and includes several syndromes such as familial adenomatous polyposis (FAP), HNPCC, *MUTYH*-associated polyposis, Peutz-Jeghers syndrome, and *PTEN*-hamartomatous tumor syndrome. These syndromes are caused by the inheritance of mutated alleles of high penetrance, major tumor suppressor genes (*APC*; FAP), or DNA repair genes (mainly *MSH2* or *MLH1*; HNPCC). Additionally, around one-fourth of cases have a familial component whose genetic basis is mostly unknown and may be due to the inheritance of “negative” alleles of genes of moderate penetrance. These alleles may have little effect individually but contribute significantly to increasing CRC risk when they accumulate in specific combinations.

Molecular subtypes of CRC with partially different alterations, biological features, and clinical behavior have been proposed. Although its value predicting patient survival has been questioned [13], a classification of

CRC in four consensus molecular subtypes (CMS) is widely accepted: CMS1, with MSI and strong immune activation; CMS2, with marked Wnt/ $\beta$ -catenin pathway activation; CMS3, with epithelial and metabolic dysregulation; and CMS4, with strong transforming growth factor (TGF)- $\beta$  activation and stromal invasion [14]. Notably, the analysis of the gene expression profiles associated with stem-like/mesenchymal, poor-prognosis CMS4 CRC has revealed that most upregulated genes are induced by TGF- $\beta$  and expressed by stromal cells: fibroblasts (cancer-associated fibroblasts or CAFs, a heterogeneous population of cells of diverse origin), leukocytes, or endothelial cells [15,16]. These CMS distribute unevenly along colon segments and rectum and may contribute to differences in clinicopathological features, patterns of metastases, clinical development and chemosensitivity for right/ascending colon, left/descending colon, and rectal tumors [17–20]. In the healthy intestine, epithelial cells and fibroblasts exchange signals in a dynamic cross-talk that ensures tissue homeostasis, which is lost in tumors. Carcinoma cells secrete factors that alter (“activate”) the phenotype of normal fibroblasts toward CAFs, which in turn change that of carcinoma cells by secreting factors that act directly on them or that modulate other stromal cells (endothelial, pericytes, immune cells) and the extracellular matrix (ECM). In line with this, CAFs secrete exosomes that promote epithelial-to-mesenchymal transition (EMT), cell stemness, metastasis, and chemotherapy resistance in CRC, and together with immunosuppressive and tumor-promoting M2 macrophage markers can predict outcome in CRC patients [21–23]. Although CAFs have been for long considered as genetically stable, work in mice models has revealed that alterations in intestinal fibroblasts can contribute to the tumorigenic process [24]. Recent data suggest that the protumorigenic effect of CAFs acting on carcinoma cells is stronger in inflammation-associated CRC than in sporadic CRC [25]. Thus, tumor stroma, particularly CAFs, seems to play a critical role in CRC progression, which agrees with the concept that tumors are composed of genetically/epigenetically altered cancer cells and recruited phenotypically altered stromal cells that interact and mutually benefit in a dynamic fashion.

Interestingly, a comprehensive analysis of premalignant human colorectal polyps has defined two distinct paths for precancer to cancer transformation involving genetic/epigenetic alterations and differential immune microenvironment features: conventional adenomas arising from Wnt-driven expansion of crypt stem cells and serrate polyps that derive from differentiated cells through metaplasia [26].

Most CRC display alterations in proto-oncogenes and tumor suppressor genes, leading to the deregulation of a few signaling pathways: Wnt/ $\beta$ -catenin, EGFR-RAS-

RAF, PI3K, p53, and TGF- $\beta$ -SMADs [27,28]. Two findings emphasize the crucial importance of the Wnt/ $\beta$ -catenin pathway in CRC. First, massive sequencing efforts have shown that over 94% of primary and up to 96% of metastatic colorectal tumors, either hypermutated or nonhypermutated, contain mutations in genes that aberrantly activate the Wnt/ $\beta$ -catenin signaling pathway [27,28]. Second, it has been reported that an intestinal stem cell gene signature that largely coincides with that induced by the activation of the Wnt/ $\beta$ -catenin pathway identifies CRC stem cells and predicts disease relapse [29].

### 1.3 The Wnt/ $\beta$ -catenin signaling pathway

Wnt signaling is fundamental for the development of multicellular organisms regulating key processes such as primary axis formation, asymmetrical stem cell division, organogenesis, and regeneration [30,31]. In the adult, Wnt signaling plays an essential role in tissue homeostasis, and its deregulation is frequently associated with cancer initiation and/or progression [32,33]. CRC is the most paradigmatic example of Wnt signaling deregulation.

The Wnt family of extracellular ligands is composed of 19 members in mammals. Wnts are secreted glycoproteins, hydrophobic due to lipid modification and of compact structure because of abundant disulfide bonds [34]. There are a great variety of Wnt receptors and coreceptors, although the bases for ligand–receptor binding specificity are mostly unknown [35]. Nevertheless, this abundance of receptors allows Wnt proteins to engage different signaling pathways [31,36]. In this chapter, we will focus on the Wnt/ $\beta$ -catenin signaling pathway or Wnt canonical pathway, which is well studied and its involvement in cancer, in particular CRC, is well documented. Other Wnt pathways are globally known as Wnt noncanonical pathways and their role in tumorigenesis is less clear, although some evidence is beginning to mount [37–39].

In the canonical pathway, Wnt proteins control the amount of free cytosolic  $\beta$ -catenin in target cells. In unstimulated epithelial cells,  $\beta$ -catenin is mostly located at plasma membrane *adherens junctions* bound to the cytoplasmic tail of the  $\text{Ca}^{2+}$ -dependent intercellular adhesion molecule E-cadherin. Free  $\beta$ -catenin in the cytoplasm is targeted for proteolysis by a multiprotein destruction complex that contains the tumor suppressor proteins APC and Axin, and the serine/threonine kinases casein kinase (CK) $\text{I}\alpha$  and glycogen synthase kinase (GSK) $3\text{-}\alpha/\beta$ . N-terminal phosphorylation within this complex primes  $\beta$ -catenin for subsequent ubiquitination by  $\beta$ -transducin repeat-containing protein ( $\beta$ -TrCP) and proteasomal degradation. Therefore, in

the absence of Wnt ligands, levels of free  $\beta$ -catenin are kept low [31,36] (Fig. 89.1).

The canonical pathway is triggered upon Wnt binding to a heterodimeric cell surface receptor composed of a member of the Frizzled family of seven-pass transmembrane receptors and LRP5 or 6, members of the LDL receptor-related protein (LRP) family. Wnt binding induces LRP5/6 phosphorylation and its subsequent interaction with Axin, which results in inactivation of the  $\beta$ -catenin destruction complex and, therefore, the accumulation of  $\beta$ -catenin in the cytoplasm [31,36]. A proportion of  $\beta$ -catenin then enters the nucleus and interacts with transcription factors of the T cell factor (TCF) family (four members, in colon preferentially TCF4 encoded by *TCF7L2* gene). In the absence of  $\beta$ -catenin, TCF proteins and some corepressors are bound to their target genes, in most cases actively repressing them.  $\beta$ -Catenin behaves as a coactivator, displacing the corepressors and reversing the regulation of TCF targets: genes that are repressed in the absence of nuclear  $\beta$ -catenin (many involved in cell proliferation, and migration/invasion) become activated, while a minority that are activated in the absence of nuclear  $\beta$ -catenin become repressed following  $\beta$ -catenin binding to TCF [36,40,41].

The Wnt/ $\beta$ -catenin pathway is additionally regulated by transmembrane E3 ubiquitin ligases ring finger protein 43 (RNF43) and zinc and ring finger 3 (ZNRF3), which constitutively promote the degradation of Frizzled receptors causing the repression of Wnt/ $\beta$ -catenin signaling. Overcoming this effect, members of the R-spondin family of proteins (RSPO1–4) bind to leucine-rich repeat-containing G protein–coupled (LGR) receptors and inhibit RNF43/ZNRF3, which leads to Wnt/ $\beta$ -catenin signaling sustaining [42,43] (Fig. 89.1). RSPOs are produced by stromal cells adjacent to the stem cell niche [44] and are necessary to maintain the stem cell compartment both in vivo and in intestinal organoids cultures [45–48]. Wnt/ $\beta$ -catenin signaling is also modulated by extracellular inhibitors that either bind and sequester Wnt proteins themselves (e.g., secreted Frizzled-related proteins or SFRP, Wnt-inhibitory factor, or WIF-1) or that physically interact with LRP receptors (e.g., Dickkopf or DKK), specifically inhibiting the canonical Wnt pathway [49].

As said before, most, if not all, sporadic CRC present an activated Wnt/ $\beta$ -catenin pathway, which is accepted as the initial step in colorectal tumorigenesis. Recurrent mutations include loss-of-function mutations in *APC* (>80%) and *RNF43* (10%), and gain-of-function mutations in *CTNNB1*/ $\beta$ -catenin (2%) and *RSPO2/3* (8%) [27,48,50,51]. Interestingly, alterations affecting these genes both in precancerous polyps and in tumors show marked mutual exclusivity [52]. Mutations in *APC* and *CTNNB1*/ $\beta$ -catenin lead to constitutive

**FIGURE 89.1** 1,25(OH)<sub>2</sub>D<sub>3</sub> exerts a multilevel antagonism of the Wnt/β-catenin signaling pathway in colon carcinoma cells. The pathway is activated upon binding of secreted Wnt factors to their plasma membrane Frizzled/LRP5/6 receptor complexes, which prevents the cytosolic degradation of β-catenin. Part of the accumulated β-catenin protein enters the cell nucleus where it acts as a transcriptional coactivator of TCF4-bound genes. 1,25(OH)<sub>2</sub>D<sub>3</sub> binding to VDR sequesters β-catenin, and therefore, it impedes the formation of transcriptionally active β-catenin/TCF4 complexes and thus, the induction of their target genes. Ligand-bound VDR upregulates the expression of *CDH1* encoding E-cadherin, which attracts cytosolic β-catenin to the plasma membrane *adherens junctions*, and of several genes including *DKK1*, *AXIN*, and *TCFL7* that contribute to inhibit the Wnt/β-catenin pathway. Additionally, 1,25(OH)<sub>2</sub>D<sub>3</sub> may inhibit the expression and secretion of IL-1β in neighbor macrophages, which activate Wnt signaling in carcinoma cells via the blockade of GSK-3β.

activation of the pathway, which is independent of Wnt ligands, while alterations in *RNF43* and *RSPO* amplify endogenous and otherwise intact Wnt/β-catenin signaling that is ligand-dependent [48]. The common consequence is the inhibition of β-catenin degradation and, therefore, the accumulation of free β-catenin. However, only a small number of CRC cells exhibit abundant β-catenin in the cytoplasm and nucleus. These cells are usually located at the tumor invasion front, in contact with the surrounding stroma. This apparent discrepancy with the model (known as the “β-catenin paradox”) suggests that in addition to mutations in components of the

destruction complex, β-catenin can be further activated by additional layers of regulation, which demonstrates the complexity of Wnt/β-catenin signaling deregulation in cancer ([53] and references therein). Accordingly, it has been demonstrated that effective nuclear accumulation of β-catenin requires additional mutations (e.g., *KRAS*) [54,55] or intensifying signals upstream the β-catenin destruction complex provided by Wnts, RSPOs, or hepatocyte growth factor (HGF) secreted by surrounding stromal cells [56,57]. In addition, loss of extracellular inhibitors of Wnt/β-catenin signaling, such as SFRP or DKK family members, is frequent in CRC and other

tumors and contributes to enhancing Wnt/ $\beta$ -catenin signaling by increasing nuclear  $\beta$ -catenin accumulation [58–62]. This results in activation of the  $\beta$ -catenin/TCF gene program that includes genes promoting proliferation and cell survival, such as *MYC* or *CCND1*/cyclin D1, as well as genes involved in loss of epithelial features and acquisition of migration capacity and other mesenchymal traits (e.g., *SNAI1/2*, *ZEB1*), a phenotypic change called EMT.

In the colon, Wnt factors and RSPOs are mostly secreted by pericryptal fibroblasts surrounding the bottom half of the colonic crypt and are essential to preserve the stem cell population that give rise to differentiation-committed transit amplifying (TA) cells. These cells move upward in the crypt where concentrations of Wnt ligands are lower, and when the Wnt/ $\beta$ -catenin pathway is eventually switched off, they undergo differentiation into absorptive enterocytes/colonocytes, mucosecretory goblet cells, or enteroendocrine cells [63–66]. Constitutive activation of the Wnt/ $\beta$ -catenin pathway due to mutation prevents TA cells differentiation and promotes the generation of adenomas/polyps [42,67]. Moreover, strong reactivation of the pathway in differentiated cells due to cooperation of inflammatory signals (e.g., NF- $\kappa$ B) with nuclear  $\beta$ -catenin results in dedifferentiation and entry into the cell cycle [68]. Likewise, loss of SMAD4 and activation of the Wnt/ $\beta$ -catenin pathway leads to dedifferentiation, cell cycle entry, reexpression of stem cell genes, and rapid adenoma formation in differentiated tissue [69].

However, despite the pivotal role that aberrant activation of the Wnt/ $\beta$ -catenin pathway plays in the development of CRC, targeting this pathway for clinical use remains elusive. Several special features may account for this including the lack of a feasible drug target (for example, kinases), the localization (nuclear) of  $\beta$ -catenin/TCF complexes, the plethora of activating factors (numerous Wnts, RSPOs, HGF, etc.), and the expected toxicity of potential inhibitors of this pathway due to the key role of Wnt/ $\beta$ -catenin signaling in many tissues and organs [36,43,70–73].

## 2. Human observational and intervention studies

A link between vitamin D and CRC is not surprising as the intestine is the organ with highest expression of the vitamin D receptor (VDR) and vitamin D is a key regulator of its physiology modulating many of its functions through the control of a high number of genes [74–76]. Some metaanalyses indicate that CRC is the neoplasia that is most clearly linked to vitamin D deficiency, but causality and the beneficial role of vitamin D in CRC prevention or treatment has not been fully demonstrated.

In 1980, Garland and Garland were the first to propose that the protective action of solar radiation on cancer risk is mediated by the vitamin D that it induces in skin [77]. Nine years later, a prospective study showed the inverse relation between the level of 25(OH)D in serum and CRC risk and mortality [78]. In recent decades, a large number of observational/epidemiological studies have analyzed the relation of solar irradiation, vitamin D dietary intake, and vitamin D status (circulating 25(OH)D) on total cancer and CRC incidence and mortality. In spite of their limitations (putative confounding effects of  $\text{Ca}^{2+}$  and other dietary components, enzymatic control of effective 1,25(OH) $_2$ D $_3$  concentrations in colon cells and the level of VDR expression, among others), many but not all studies indicate a protective action of vitamin D on CRC risk [1,79–83]. A metaanalysis supports that low plasma 25(OH)D level associates with poorer CRC patient survival, particularly in those with the VDR rs11568820 GG single-nucleotide polymorphism (SNP) [84]. Interestingly, a large study ( $n = 2592$ ) has revealed that the survival advantages in CRC patients with adequate vitamin D strongly depend on antioxidant status and are more pronounced in cases of low antioxidant capacity [85].

Trials on the effects of vitamin D supplementation on total cancer or CRC responsiveness and their results are controversial [86–89]. Unfortunately, published trials have major limitations or deficiencies: disparity to evaluate vitamin D status (sometimes by direct measures of circulating 25(OH)D and others indirectly by analyzing sun exposure, food intake composition, or vitamin D target genes expression), low doses of vitamin D that did not increase serum 25(OH)D concentration, calcium cotreatment, and insufficient analysis of vitamin D status and confounding factors [90–92]. Other limitations are low compliance, short duration, and follow-up, including only old population and questionable statistics analyses [93]. Some studies focused mainly on postmenopausal women, who probably do not represent the general population in terms of vitamin D responsiveness. Another common problem of these studies is a nonappropriated placebo group, with off-protocol vitamin D (and/or calcium) supplementation allowed. Furthermore, two major additional drawbacks common to most studies are that many participants were not deficient in 25(OH)D levels, and the lack of subgroup analysis. Clearly, (1) populations already replete of vitamin D are not expected to benefit from additional vitamin D treatment, and (2) the separate analysis of racial or body mass index subgroups may reveal beneficial action that are masked in global population analyses, for example, in the VITAL trial [93–98].

Moreover, few trials take into consideration individual genetics, polymorphisms in VDR, GC, CYP27B1,

*CYP24A1*, *DHCR7*, and *CYP2R1* genes that may modulate serum 25(OH)D levels and vitamin D action [86,99–101]. Thus, GC isoforms (rs4588 and rs2282679) may modulate the association of vitamin D status with mortality of CRC patients [100,102,103]. Globally, data on the importance of *VDR* genotype for CRC and other cancer types are conflicting, and it is not possible to rise any conclusion about the putative modulation by *VDR* polymorphisms of cancer risk, which may be modified by ethnicity and vitamin D status [104,105]. Remarkably, a comprehensive study using Mendelian randomization and a large set of variants (74 SNPs) suggests that low 25(OH)D level is unlikely to be a causal risk factor for most cancers [106].

An intriguing confounding factor is immune status, specifically the systemic inflammatory response. Vitamin D regulates many aspects of the immune function and has antiinflammatory effects; conversely, chronic inflammation, which is common in many types of cancer, is associated with low serum 25(OH)D concentrations [82,107]. These findings have led some authors to propose that many cancer patients have low serum 25(OH)D as a consequence of their neoplastic process or ad hoc treatment, that is, a reverse causality of the disease status [108]. Supporting this idea and the reduced response to vitamin D of severely ill patients at intensive care units, corticoids commonly given to these patients can inhibit the hepatic hydroxylation of vitamin D to 25(OH)D. Interestingly, Song and colleagues [109] reported that high plasma 25(OH)D level is associated with lower risk of the CRC subtype characterized by a high intratumoral periglandular immune/lymphocytic reaction. Further research is required to ascertain whether, as proposed by the authors, these results imply that host immunity may serve as a potential biomarker to predict benefits of vitamin D supplementation for CRC prevention.

Based on data from preclinical studies using cultured cells and animal models, several finished and ongoing clinical trials use combinations of vitamin D compounds with folic acid, omega-3 fatty acids, calcium, and antiinflammatory drugs (such as aspirin) or chemotherapeutic agents for CRC prevention or treatment. Furthermore, the long-term prevalent idea that vitamin D can be beneficial only in the early stages of cancer has been broadened and challenged by recent data on metastatic CRC patients: high circulating 25(OH)D levels in patients with CRC liver metastasis treated with percutaneous radiofrequency ablation predicted longer overall survival (OS) and time to recurrence [110] and improved also OS and progression-free survival (PFS) of metastatic CRC patients in a randomized phase III trial (CALGB/SWOG 80405) of chemotherapy plus bevacizumab (anti-VEGF antibody), cetuximab (anti-EGFR antibody), or both [90,111].

There is a clear need to wait for the results of well-designed randomized controlled trials selecting vitamin D-deficient patients, using appropriate placebo groups and vitamin D doses that adequately analyze baseline and follow-up vitamin D status, long follow-up, stratification of the results into subpopulations, and ideally individual vitamin D responsiveness. These studies are required to definitively assess the potential utility of *VDR* agonists, and to accept or reject the reverse causality of vitamin D deficiency in CRC and total cancer. Vitamin D-free placebos are, however, difficult to accomplish for ethical reasons, and, importantly, as discussed by Feldman and colleagues [112], there are still a number of questions that need to be addressed, including the optimal form of vitamin D (cholecalciferol, 1,25(OH)<sub>2</sub>D<sub>3</sub>, or analogs), doses, regimen (frequent low doses seem to be more efficient than large occasional bolus), and drug combination to be used.

Overall, available results suggest that vitamin D compounds, alone or more probably in combination with other agents, could help in the prevention and perhaps treatment of CRC. Observational and intervention studies and metaanalyses point toward an effect of vitamin D compounds reducing CRC progression and mortality, rather than on incidence [87,90–92,94,113–116]. Interestingly, a recent study has shown that high total vitamin D intake associates with decreased risks of EOCRC and precursors in a cohort of young women [1].

In support of a beneficial role of vitamin D in CRC, a large number of mechanistic preclinical studies, which are summarized in the following sections, show a variety of protective, antitumoral effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> and other *VDR* agonists on CRC cells, several animal models of CRC, and, recently, also on CRC-associated fibroblasts and stem cells.

### 3. Expression of vitamin D hydroxylases and the vitamin D receptor in colorectal cancer

#### 3.1 Vitamin D hydroxylases

CRC cell responsiveness to vitamin D metabolites is mainly determined by the level of 1,25(OH)<sub>2</sub>D<sub>3</sub> within the cell and the degree of *VDR* expression. The intracellular level of 1,25(OH)<sub>2</sub>D<sub>3</sub> depends on the amount of circulating 25(OH)D and 1,25(OH)<sub>2</sub>D<sub>3</sub>, and on the expression and activity of the enzymes responsible for its synthesis (*CYP2R1*, *CYP27B1*) and degradation (*CYP24A1*).

Work by many groups show that normal and malignant colon epithelial cells contain different amounts of *CYP27B1* and *CYP24A1*. In 1997, Cross and colleagues showed that cultured CRC Caco-2 cells could synthesize

1,25(OH)<sub>2</sub>D<sub>3</sub>, 1,24,25(OH)<sub>3</sub>D<sub>3</sub>, and 24,25(OH)<sub>2</sub>D<sub>3</sub> from 25(OH)D<sub>3</sub>, which suggests that they express both CYP27B1 and CYP24A1 enzymes [117]. Similar 25(OH)D<sub>3</sub> metabolism was found in primary cultures obtained from human CRC [118]. In addition, several studies reported that normal colon epithelial cells and most colorectal tumors express CYP27B1, and expression differences between normal and tumor tissues have been found [118–127]. Thus, it has been proposed that CYP27B1 expression is upregulated in moderately and well-differentiated human colorectal tumors and drastically decreases in poorly differentiated carcinomas [118,119,122,124,125]. Accordingly, CYP27B1 is expressed at similar levels in normal colonic epithelium as in aberrant crypt foci, polyps, and CRC irrespective of tumor differentiation, but its expression is lower in tumor cells metastasizing to regional lymph nodes [126]. More recently, CYP27B1 and CYP2R1 genes have been found upregulated in CRC samples compared with the adjacent nontumoral tissue [128]. In addition, SNPs in CYP27B1 such as rs28934604, rs58915677, rs13377933, and rs2229103 [129] or rs4646536 and rs10877013 [130,131] have been associated to the occurrence of CRC. In a later study, Latacz and colleagues have suggested a protective role of the T allele at the polymorphic site in rs10877012 (T/G) polymorphism in CYP27B1 gene in CRC patients [132]. In summary, available data suggest that CYP27B1 expression and 1,25(OH)<sub>2</sub>D<sub>3</sub> synthesis may be a protective mechanism of colon normal and cancerous cells to control their own growth autocrinally and/or paracrinally. This mechanism is lost in advanced CRC [119,124,125,133].

In contrast to CYP27B1, a number of studies have reported that CYP24A1 is expressed at low levels in normal colon epithelial cells, whereas it is overexpressed in colorectal tumors [118,125,134–137]. Remarkably, CYP24A1 upregulation seems to be an early event in CRC progression, as it has already been observed in a proportion of colorectal adenomas [135]. Moreover, CYP24A1 expression in colorectal tumors strongly correlates with that of the proliferation markers Ki67, CDC6, MCM2, MCM4, and MCM7, which suggests that elevated CYP24A1 levels may provide a growth advantage to the tumor [135,136]. In line with this, cultured and xenografted CRC cells overexpressing CYP24A1 proliferate faster than controls, and the tumors that they generate in immunosuppressed mice are more aggressive [138]. Regarding the mechanism underlying CYP24A1 upregulation, Höbaus and colleagues have reported that 60% of CRC show an increase in the CYP24A1 gene copy number and that this number directly correlates with CYP24A1 expression [136]. Similarly, a study using quantitative measurement of the DNA copy number across amplified regions had previously proposed CYP24A1 as a candidate oncogene in breast cancer [139]. Höbaus and

colleagues did not find differences in the methylation status of the CYP24A1 gene promoter between normal and tumor colon tissue or between colorectal tumors with high or low CYP24A1 expression, thus excluding DNA hypomethylation as a possible cause of CYP24A1 upregulation in CRC [136].

Polymorphisms in CYP24A1 gene affect the response to vitamin D supplementation in CRC patients [140]. A study analyzing the copy number variation in Chinese population indicated that in 51.1% of CRC samples, CYP24A1 was amplified when compared with matched adjacent normal tissues [141]. In an African American US cohort, rs6022990 SNP in the CYP24A1 gene was linked with left-sided CRC ( $P = 0.018$ ) [142], while four other SNPs showed a correlation with the risk of CRC [143] and the rs4809957 A > G polymorphism may lead to a worse prognosis [130]. Recently, Chain and colleagues have reported that some CYP24A1 polymorphisms in CRC patients of the Jiamusi population were significantly associated with clinical features such as poor differentiation or tumor type [144]. Another study has identified squalene epoxidase, an enzyme that controls cholesterol biosynthesis and is upregulated in CRC associated with poor prognosis, as a strong inducer of CYP24A1 and MAPK signaling [145].

High CYP24A1 expression in CRC cells must lead to the depletion of intracellular 1,25(OH)<sub>2</sub>D<sub>3</sub> levels through their rapid conversion into less active metabolites, thus limiting the antitumor effects of 1,25(OH)<sub>2</sub>D<sub>3</sub>. Interestingly, a combination treatment using 1,25(OH)<sub>2</sub>D<sub>3</sub> and CYP24A1 inhibitors exerts a significantly greater inhibition of CRC cell proliferation than 1,25(OH)<sub>2</sub>D<sub>3</sub> alone. This suggests that such combination therapy should be explored for CYP24A1-overexpressing colorectal tumors to extend the bioavailability of 1,25(OH)<sub>2</sub>D<sub>3</sub> [138,146]. In general, the downregulation of CYP27B1 and the upregulation of CYP24A1 found in advanced CRC would lead to attenuated 1,25(OH)<sub>2</sub>D<sub>3</sub> synthesis and accelerated 1,25(OH)<sub>2</sub>D<sub>3</sub> catabolism, thus reducing VDR activation and causing partial or total resistance to the antitumor effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> [118,133].

### 3.2 Vitamin D receptor

Cellular response to 1,25(OH)<sub>2</sub>D<sub>3</sub> crucially depends on VDR expression levels. Normal colon epithelial cells and several CRC cell lines express VDR and respond to 1,25(OH)<sub>2</sub>D<sub>3</sub>. However, certain CRC cell lines have lost VDR expression and thus have become 1,25(OH)<sub>2</sub>D<sub>3</sub>-resistant [147–150]. Remarkably, well-differentiated CRC cell lines display higher VDR levels than poorly differentiated cells [147]. Several studies have analyzed VDR expression in human CRC biopsies and compared it with that found in normal colonic tissue. Overall, the results suggest that VDR expression is induced in

precancerous lesions and early steps of colorectal tumorigenesis (aberrant crypt foci, polyps/adenomas), but decreases in advanced stages (carcinomas) [119,126,127,134,137,147,151–158]. Moreover, VDR levels are extremely low in CRC lymph node metastases [126]. Accordingly, elevated VDR expression in primary tumors is associated with high differentiation, absence of node involvement, and good prognosis in CRC [153,156,158–160]. VDR levels are also reduced in the colonic mucosa of UC patients. Remarkably, VDR expression is significantly decreased in long-term patients (over 10 years) and in patients with UC-associated dysplasia or CRC [149].

As a cellular response to  $1,25(\text{OH})_2\text{D}_3$  requires VDR expression, the downregulation of VDR observed in advanced CRC must generate tumor resistance to a therapy with vitamin D compounds and to endogenously synthesized  $1,25(\text{OH})_2\text{D}_3$ . It is, however, worth noting that studies mentioned referred only to carcinoma cells and not to stromal cells. The analysis of the expression of VDR in 658 patients with CRC with prolonged clinical follow-up indicated that high VDR expression in stromal fibroblasts is associated with OS and PFS independently of the expression in carcinoma cells, with important effects at the level of gene expression that will be discussed in the following sections [160]. Conversely, CRC patients have higher adipose tissue VDR mRNA and protein levels than healthy individuals, which may indicate a compensatory mechanism in response to the low blood  $25(\text{OH})\text{D}$  levels in these patients [161].

Our group has studied the mechanisms responsible for VDR downregulation during CRC progression. We reported that the transcription factor SNAIL1, encoded by the *SNAIL1* gene, binds to three E-boxes in the proximal human *VDR* gene promoter and represses its expression in CRC cells. In addition, SNAIL1 reduces *VDR* RNA half-life [155]. Subsequently, we found that, in addition to SNAIL1, its family member SNAIL2 (also known as SLUG, encoded by the *SNAIL2* gene) represses VDR expression through the same E-boxes in the *VDR* gene promoter, and blocks the antitumor effects of  $1,25(\text{OH})_2\text{D}_3$  in CRC cells. Moreover, SNAIL1 and SNAIL2 show an additive repressive effect on the activity of the *VDR* gene promoter [158]. In line with this, SNAIL2/SLUG inhibits the enhanced sensitivity to radiation mediated by  $1,25(\text{OH})_2\text{D}_3$  in DLD-1 and HCT116 CRC cells [162].

SNAIL1 and SNAIL2 are inducers of EMT, a process that takes place physiologically in several developmental situations such as mesoderm formation and neural crest migration and is reactivated in adults in certain conditions such as wound healing, fibrosis, and cancer. Through this process, epithelial cells that overexpress these transcription factors undergo gene expression

reprogramming characterized by the downregulation of epithelial genes and the induction of mesenchymal genes. This leads to a drastic phenotypic change from highly compact, polarized, and adhesive epithelial cells to motile individual mesenchymal cells that can degrade the extracellular matrix and develop a migratory and invasive phenotype [163–167]. We found that nearly 75% of human colorectal tumors exhibit higher SNAIL1 and/or SNAIL2 levels than those observed in normal colonic tissue and that this upregulation is significantly associated with diminished VDR expression. Indeed, the lowest VDR levels were detected in those tumors that overexpress both transcription factors [155,156,158]. We also showed that elevated SNAIL1 expression in colon tumors is associated with VDR downregulation in the histologically normal tissue adjacent to the tumor, which suggests that SNAIL1-expressing colorectal tumors secrete signals that paracrinally modulate VDR expression in neighboring cells [168]. Other studies further support the repression of VDR by SNAIL factors in CRC. Silibinin, a flavonolignan with anticancer properties that downregulates SNAIL1 and SNAIL2, increases VDR levels and restores  $1,25(\text{OH})_2\text{D}_3$  antitumor action in  $1,25(\text{OH})_2\text{D}_3$ -resistant CRC cells [169]. Similarly, the reduced SNAIL1 expression detected in colon tumors that have been chemically induced in mice carrying an *Egfr* hypomorphic mutation (*Egfr*<sup>wa2/wa2</sup>) is accompanied by *Vdr* upregulation [170]. In addition, Knackstedt and colleagues described that the low colonic *Vdr* expression observed in a murine model for acute colitis is associated with an increase in *Snail* [171].

These data indicate that the induction of SNAIL1 and/or SNAIL2 during CRC progression is responsible for VDR downregulation. The expression of both transcription factors is probably required to achieve maximum VDR repression. Our results also imply that CRC patients with high tumor expression of SNAIL1 and/or SNAIL2 would be poor responders to the antitumor effects of  $1,25(\text{OH})_2\text{D}_3$  compounds. Since these factors are frequently upregulated in advanced CRC (associated with the acquisition of migratory and invasive properties by the tumor cells), it was previously thought that VDR agonists should be preferentially used in CRC as preventive agents in high-risk populations and/or as therapeutic drugs for patients in early stages of the disease. Interestingly, we have reported that CRC-associated fibroblasts express VDR and that  $1,25(\text{OH})_2\text{D}_3$  treatment inhibits their protumoral properties and phenotype. Accordingly, high VDR expression in these fibroblasts is significantly associated with a favorable clinical outcome in a large cohort of metastatic CRC patients [160]. These results substantially broaden the vision of the applicability of VDR agonists for CRC, as they suggest that these compounds could exert

therapeutic anticancer effects in CRC patients whose tumor fibroblasts express VDR even if their carcinoma cells lack VDR expression.

The repression of VDR by transcription factors of the SNAIL family is not exclusive to CRC. SNAIL1 and SNAIL2 have been described to downregulate VDR expression and block the antitumor action of 1,25(OH)<sub>2</sub>D<sub>3</sub> in human osteosarcoma and breast cancer cells, respectively [172,173]. As SNAIL factors are overexpressed in several neoplasias [174,175] and reduced VDR levels have been found in a variable proportion of melanomas and breast, lung, and ovarian tumors [134,176–179], it is reasonable to propose that SNAIL proteins may also be involved in VDR downregulation in these malignancies.

We found that other transcription factors that are also inducers of EMT, such as ZEB1, ZEB2, TWIST1, or E47, do not modify the activity of the proximal human VDR gene promoter in SW480-ADH CRC cells [158]. However, Lazarova and colleagues reported that ZEB1 binds to two distal E-boxes in the murine *Vdr* promoter and induces its expression in human SW620 CRC cells, but not in other CRC cells such as HCT116 [180]. Moreover, studies using different CRC patient cohorts show an absence of correlation or a significant direct correlation between ZEB1 and VDR expression in colon tumors [156,168,181]. Furthermore, Peña and colleagues described a stronger direct correlation in colorectal tumors with elevated expression of the transcriptional coactivator p300 [181]. In addition, Maurer and colleagues reported that the transcription factor WT1 potentiates 1,25(OH)<sub>2</sub>D<sub>3</sub> action by inducing VDR transcription in HT29 CRC cells [182].

Several evidence suggest that VDR posttranscriptional repression by microRNAs (miRs) may also be involved in the reduction of VDR levels found in CRC. *miR-27b* and *miR-298* inhibit VDR expression in LS180 CRC cells [183], and *miR-346* mediates the downregulation of VDR expression promoted by the proinflammatory cytokine TNF- $\alpha$  in HCT116 CRC cells [184]. Accordingly, VDR repression correlates with high TNF- $\alpha$  and *miR-346* levels in an experimental colitis mouse model and in human biopsies from patients with IBDs [184]. In addition, *miR-125b*, which is overexpressed in CRC metastases [185], downregulates VDR expression and reduces 1,25(OH)<sub>2</sub>D<sub>3</sub> action in breast cancer cells [186]. The expression of the long noncoding (lnc)RNA *H19* negatively correlates with that of VDR in primary colon tissues and CRC cells, and its overexpression reduces VDR expression through *miR675-5p* [187], while in Caco-2 cells, *miR-372/miR-373* repress VDR expression [188].

VDR expression is also subjected to regulation by RNA-binding proteins. HuR binds to mouse *Vdr* RNA via its 3'-untranslated region (UTR) and enhances its translation in intestinal epithelial cells [73]. Conversely,

the zinc finger protein 36 (ZFP36) has been reported to bind the 3'-UTR of VDR mRNA, leading to its degradation in colonic epithelial cells under inflammatory conditions [189].

Interestingly, Kure and colleagues showed that *KRAS* and *PIK3CA* activating mutations, which are, respectively, found in 30%–45% and 10%–20% of human CRC, are independently associated with high tumor VDR expression [157]. In contrast, two other studies reported that transforming *Hras* inhibits Vdr expression in murine HC11 mammary cells and NIH3T3 fibroblasts [190–192]. This implies species-, cell type-, and/or family member-dependent regulation of VDR by RAS. Nearly half of human CRC harbor *TP53* inactivating mutations. While Kure and colleagues did not find a statistical association between the expression of p53 and VDR proteins in a cohort of CRC patients [157], Maruyama and colleagues showed that p53 and its family members p63 and p73 induce VDR expression in cultured CRC cells [193]. Notably, mutated p53 interacts with VDR, increases nuclear VDR levels, and modulates the 1,25(OH)<sub>2</sub>D<sub>3</sub> response in colon and other types of cancer cells, changing 1,25(OH)<sub>2</sub>D<sub>3</sub> from proapoptotic to antiapoptotic [194]. Moreover, a positive correlation between VDR and CDX2 has been reported, and low expression of VDR or CDX2 is associated with the sensitivity to chemotherapy and BRAF and PI3K-mTOR inhibitors [195]. Together, these data suggest that the mutational status of CRC patients may influence their response to therapies based on VDR agonists.

Several SNPs of VDR gene have been studied in relation to CRC occurrence and prognosis, but only few of them seem to affect the expression of the VDR gene in relation of CRC. There was not a correlation between *BsmI*, *FokI*, *ApaI*, and *TaqI* VDR polymorphisms and CRC risk in the overall analyses. However, *ApaI* and *BsmI* loci are associated with CRC risk in elderly and female patients, respectively, in Saudi population [196]. Another study indicated that *ApaI* and *TaqI* VDR SNPs increase, while *BsmI* reduces the risk of CRC in Saudi population [197]. Similarly, in the Newfoundland population, a multiple testing adjustment revealed a trend for an association between VDR *BsmI* polymorphism rs1544410 and OS of CRC patients (*p*-adjusted = 0.058): G-allele was related to worse OS in comparison with the A-allele [198]. Fedirko and colleagues did not find an association between VDR (*FokI* and *BsmI*) and survival [199]. Conversely, Cho and colleagues studied the association of VDR *FokI* polymorphism with CRC risk and found an inverse association of f allele [200]. Messaritakis and colleagues found a significant association between all these four polymorphisms of VDR and CRC, significantly associated with stage IV, *KRAS* mutations, and Toll-like receptor (TLR) genetic variants. Besides, using multivariate analysis, they found that tt,

aa, and ff genotypes are independent factors associated with decreased OS [201]. Although no SNPs individually affect the risk of CRC, taB and tAb might increase the possibility of CRC development [202].

Some natural compounds have been reported to modulate the colonic vitamin D system. The steroid 17 $\beta$ -estradiol and certain phytoestrogens increase VDR and CYP27B1 expression but reduce that of CYP24A1 in cultured CRC cells and in the mouse and rat colon [203–208]. Accordingly, 17 $\beta$ -estradiol-based postmenopausal hormone replacement therapy induces VDR expression in the human rectal mucosa [209]. Dietary calcium may also regulate the colonic vitamin D system, as a low-calcium diet significantly increases CYP24A1 expression in the mouse colon [125,210–212], while reduced calcium concentration in the culture medium of Caco-2/AQ CRC cells induces VDR levels [211]. Moreover, a randomized, double-blinded placebo-controlled clinical trial indicated that calcium supplementation for 6 months reduced the expression of CYP24A1 in the normal-appearing rectal mucosa of colorectal adenoma patients [213]. Remarkably, a soy-enriched diet (which contains high levels of phytoestrogens) counteracts the increase of colonic CYP24A1 expression promoted by low dietary calcium in mice [214]. Furthermore, the short-chain fatty acid butyrate increases VDR expression and enhances the prodifferentiation action of 1,25(OH) $_2$ D $_3$  in human CRC cells [215,216]. Therefore, CRC patients' nutritional status and the use of these compounds in combination with 1,25(OH) $_2$ D $_3$  analogs may modulate tumor responsiveness to 1,25(OH) $_2$ D $_3$ , and potentially reduce the putative resistance caused by the alteration of the vitamin D system at advanced stages of CRC progression.

## 4. Mechanism of action of 1,25(OH) $_2$ D $_3$ in colorectal cancer

### 4.1 Antagonism of the Wnt/ $\beta$ -catenin pathway by 1,25(OH) $_2$ D $_3$ in colon cancer

Our group was a pioneer in the discovery of antagonism between 1,25(OH) $_2$ D $_3$ /VDR and the Wnt/ $\beta$ -catenin signaling pathway in CRC cells [148]. The key role of this pathway for CRC initiation and progression (see Sections 1.2 and 1.3) makes this finding highly relevant. In recent years, we and others have revealed a series of mechanisms by which 1,25(OH) $_2$ D $_3$  interferes the Wnt/ $\beta$ -catenin signaling (Fig. 89.1).

#### 4.1.1 Enhancement of VDR- $\beta$ -catenin protein–protein interaction

VDR physically interacts with  $\beta$ -catenin inside the cell nucleus, and in this way, it competes and interferes

the binding between  $\beta$ -catenin and TCF [148]. This results in a decrease in the number of transcriptionally active  $\beta$ -catenin/TCF complexes, which hampers the expression of  $\beta$ -catenin/TCF target genes such as *MYC*, *TCF1*, *PPARG*, *CD44*, *LEF1*, and *AXIN2*. Interestingly, although VDR- $\beta$ -catenin interaction is exacerbated by 1,25(OH) $_2$ D $_3$ , it also takes place in the absence of the hormone, which suggests that VDR binding to  $\beta$ -catenin is partially independent of 1,25(OH) $_2$ D $_3$  [148].

These findings were later confirmed by Shah and colleagues, who showed that the C-terminal region of  $\beta$ -catenin and the C-terminal activator function-2 (AF-2) motif of VDR were the main domains involved in the interaction [217]. In addition, Egan and colleagues reported that binding between  $\beta$ -catenin and VDR was potentiated by the wild-type APC protein and that the VDR ligand lithocholic acid (LCA) also enhanced this interaction, although less strongly than 1,25(OH) $_2$ D $_3$  [218]. Nevertheless, despite the antagonistic effect of 1,25(OH) $_2$ D $_3$ /VDR on Wnt/ $\beta$ -catenin signaling,  $\beta$ -catenin potentiates—rather than hampers—VDR-mediated transcription [148,217,218].

#### 4.1.2 Induction of E-cadherin

Loss of E-cadherin expression is frequent during the early progression of different types of cancers and is associated with the acquisition of invasive properties by tumor cells. Therefore, E-cadherin is considered a suppressor of invasion [219]. We reported that 1,25(OH) $_2$ D $_3$  upregulates *CDH1*/E-cadherin in CRC cells by a transcriptional mechanism that requires protein synthesis de novo [148]. In addition, we found a direct correlation between VDR and *CDH1*/E-cadherin RNA levels in human colon tumors [148,156]. Concomitant with the acquisition of a more differentiated phenotype, 1,25(OH) $_2$ D $_3$ -mediated expression of E-cadherin also resulted in redistribution of  $\beta$ -catenin from the nucleus of CRC cells to the plasma membrane *adherens junctions* where it binds to the cytoplasmic tail of E-cadherin. Consequently, in the presence of 1,25(OH) $_2$ D $_3$ , fewer molecules of  $\beta$ -catenin were available in the nucleus for TCF binding, which led to reduced expression of  $\beta$ -catenin/TCF target genes [148]. Thus, *CDH1*/E-cadherin induction has prodifferentiation, antiproliferative, and antimigratory effects that probably contribute to the antitumoral action of 1,25(OH) $_2$ D $_3$  in CRC. Remarkably, similar results have been reported by Gröschel and colleagues using the nonmalignant colonic adenoma cell line LT97 [220].

Several mechanisms contribute to the upregulation of *CDH1*/E-cadherin by 1,25(OH) $_2$ D $_3$  in CRC cells including the activation of the RhoA-ROCK and p38MAPK-MSK1 protein kinase pathway [221], the expression of the protease inhibitor cystatin D [222], the inhibition of the Sprouty receptor tyrosine kinase

signaling antagonist-2 (*SPRY2*) gene [223], and the induction of the KDM6B/Jumonji C (JmJC) domain-containing protein (JMJD) 3 histone H3 lysine demethylase [224]. Interestingly, activation of most of these effectors was also required for Wnt/ $\beta$ -catenin antagonism by 1,25(OH)<sub>2</sub>D<sub>3</sub>. This supports a close relation between E-cadherin upregulation and inhibition of  $\beta$ -catenin/TCF-mediated transcription. However, induction of E-cadherin is not an absolute requirement for 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated antagonism of Wnt/ $\beta$ -catenin signaling, since this has also been observed in the E-cadherin-negative LS174T cell line [148]. Induction of E-cadherin by 1,25(OH)<sub>2</sub>D<sub>3</sub> and concomitant inhibition of Wnt/ $\beta$ -catenin signaling have also been reported in other cell types [225,226].

As a result of its repressive effect on VDR expression, SNAIL1 blocks the induction of E-cadherin expression and the acquisition of an epithelial phenotype promoted by 1,25(OH)<sub>2</sub>D<sub>3</sub>. Consequently, in SNAIL1-expressing cells treated with 1,25(OH)<sub>2</sub>D<sub>3</sub>,  $\beta$ -catenin does not translocate from the nucleus to the *adherens junctions* at the plasma membrane, and Wnt/ $\beta$ -catenin signaling remains active. Accordingly, SNAIL1 abrogates the inhibitory effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on the proliferation and migration of cultured CRC cells and the antitumor action of the 1,25(OH)<sub>2</sub>D<sub>3</sub> analog EB1089 in such cells xenografted in immunosuppressed mice [155,227].

#### 4.1.3 Regulation of DKK1 and DKK4

1,25(OH)<sub>2</sub>D<sub>3</sub> induces the expression of the *DKK1* gene in CRC cells, and there is a significant direct correlation between VDR and *DKK1* RNA expression in tumor biopsies from CRC patients [228]. In line with this, dietary vitamin D intake is inversely associated with *DKK1* promoter methylation in a large cohort of CRC patients [229]. As said before, *DKK1* is a member of the *DICKKOPF* gene family that encodes secreted proteins that bind to LRP5/6 and function as extracellular inhibitors of Wnt/ $\beta$ -catenin signaling [230]. Binding of *DKK1* to LRP5/6 blocks the interaction between Wnt, Frizzled, and LRP5/6 and instead induces the formation of a complex with another *DKK1* receptor named Kremen, which leads to LRP5/6 endocytosis [231,232]. Both mechanisms result in the inhibition of Wnt/ $\beta$ -catenin signaling.

Upregulation of *DKK1* by 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC cells is expected to have greatest impact in Wnt ligand-dependent tumors such as those with mutations in *RNF43* or *RSPO2/3*, while it should be less relevant in tumors with a constitutive active Wnt/ $\beta$ -catenin pathway due to mutations in intracellular effectors such as *APC* or *CTNNB1*/ $\beta$ -catenin. However, it has been shown that CRC cells can respond to exogenous and autocrine Wnt ligands that further activate the Wnt/ $\beta$ -catenin signaling pathway despite having mutations that

stabilize  $\beta$ -catenin [57]. Moreover, our group and others have suggested that *DKK1* might have antitumor effects that are independent of Wnt/ $\beta$ -catenin inhibition [58,233–235], and we have also demonstrated that a proportion of *DKK1* protein is present within the nuclei of CRC cells and healthy small intestine and colon mucosa cells. Nuclear *DKK1* protein locates at specific chromatin sites of active transcription and regulates several cancer-related genes that are involved in the detoxification of chemotherapeutic agents including the cancer stem cell marker aldehyde dehydrogenase 1A1 (*ALDH1A1*) and Ral-binding protein 1-associated Eps domain-containing 2 (*REPS2*) [236]. *DKK1* expression is lost during CRC progression [61,236], partly due to gene promoter methylation [58,60,237,238], which suggests a tumor suppressor role. However, we have demonstrated that nuclear *DKK1* expression remains high in around 15% of CRC patients and is associated with decreased PFS after chemotherapy administration and OS [236]. Therefore, we proposed that nuclear *DKK1* is a marker of chemoresistance at later stages of CRC progression, when VDR expression is lost in a high proportion of tumors.

Interestingly, Postigo and colleagues have reported that EMT transcription factor ZEB1 cooperates with  $\beta$ -catenin/TCF in inducing *DKK1* expression, which leads to downregulation of senescence-associated histone variant macroH2A1 promoting senescence escape and EMT. This ZEB1/*DKK1* pathway engages also mutant p53, MDM2, and CtBP [239]. These authors have also shown that high expression of ZEB1 and *DKK1* predicted poor outcome in a group of patients in which macroH2A1 expression was low [239,240].

*DKK4*, another *DICKKOPF* family member, is repressed by 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC cells by a transcriptional mechanism involving binding of VDR and SMRT corepressor to a region adjacent to its transcription start site [241]. Notably, our group and others have shown that despite its reported function as a weak Wnt inhibitor, *DKK4* is overexpressed in human colon tumors and in IBD [241–244] and that an inverse correlation exists between the levels of VDR and *DKK4* RNA in human colorectal tumors [241]. In line with this, ectopic expression of *DKK4* increased the migration, invasion, and proangiogenic properties of CRC cells [241], and it has been found to enhance resistance to chemotherapeutics in CRC cells [245], which suggests that the inhibition of *DKK4* by 1,25(OH)<sub>2</sub>D<sub>3</sub> may contribute to the antitumor effects of 1,25(OH)<sub>2</sub>D<sub>3</sub>.

In summary, available data indicate that *DKK* proteins are a family of Wnt antagonists with additional functions whose pharmacological potential as cancer therapeutics remains unclear but that seems to mediate some of the protective actions of 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC [246].

The mechanisms of Wnt/ $\beta$ -catenin antagonism reported before are completely dependent on VDR expression, as they do not take place in VDR-negative human CRC cells (SW480-R and SW620) or in VDR-positive cells (SW480-ADH) in which expression of VDR has been silenced either by using specific shRNA or by ectopic expression of SNAIL1 or SNAIL2 [148,155,158,227,228,247]. Since SNAIL1 is induced by Wnt/ $\beta$ -catenin signaling [248–250], it may constitute a mechanism to bypass the inhibitory effect of  $1,25(\text{OH})_2\text{D}_3$  on this pathway. In addition, we have found that several less calcemic analogs of  $1,25(\text{OH})_2\text{D}_3$ , such as EB1089, KH1060, MC903, WU515, CD578, and WY1113, antagonize Wnt/ $\beta$ -catenin signaling in human CRC cells to a similar or even greater extent than the hormone itself [148,251]. Likewise, Xu and colleagues reported similar results with the BTW and QW analogs in breast and CRC cells [225].

#### 4.1.4 Other mechanisms of Wnt/ $\beta$ -catenin antagonism by $1,25(\text{OH})_2\text{D}_3$ in cultured carcinoma cells

Beildeck and colleagues have reported that  $1,25(\text{OH})_2\text{D}_3$  induces the expression of the *TCF7L2/TCF4* gene in CRC cells by a VDR-dependent indirect mechanism and also that Tcf4 protein levels were lower in the mammary gland of *Vdr*<sup>-/-</sup> mice than in wild-type mice [252]. These authors suggested that upregulation of TCF4 might have a protective role on CRC since it has been reported that TCF4 inhibits the growth of CRC cells [253]. In contrast, Gröschel and colleagues showed that the colon of healthy mice that were fed a high vitamin D diet showed reduced expression of both  $\beta$ -catenin and TCF4 [220]. They also found that  $1,25(\text{OH})_2\text{D}_3$  diminishes the nuclear levels of  $\beta$ -catenin in LT97 colon microadenoma cells, and thus, it inhibits the expression of Wnt target genes such as *BCL2*, *CCND1/cyclin D1*, *SNAIL1*, *CD44*, and *LGR5* [220]. In this regard, Li and colleagues have recently reported that  $1,25(\text{OH})_2\text{D}_3$  suppressed gastric cancer cell growth through downregulating *CD44* expression, which is concomitant to the inhibition of the Wnt/ $\beta$ -catenin pathway [254].

Calcipotriol, a potent nonhypercalcemic  $1,25(\text{OH})_2\text{D}_3$  analog, inhibits Wnt/ $\beta$ -catenin signaling and decreases the level of the Wnt coreceptor LRP6 in pancreatic ductal adenocarcinoma cell lines, through a mechanism involving transcriptional upregulation of the low-density lipoprotein receptor adaptor protein 1 [255]. By contrast,  $1,25(\text{OH})_2\text{D}_3$ /VDR has been shown to induce the Wnt inhibitor *AXIN1* in CRC cells through a VDRE located in the gene promoter [256]. Interestingly, it has been reported that VDR upregulates the expression of long noncoding RNA (lncRNA) *TOPORS antisense RNA 1 (TOPORS-AS1)* in ovarian cancer, which in turn inhibits Wnt/ $\beta$ -catenin signaling by increasing

$\beta$ -catenin phosphorylation and suppressing the expression of *CTNNB1/ $\beta$ -catenin*. This mechanism requires the RNA-binding protein heterogeneous nuclear ribonucleoprotein A2B1 (hnRNPA2B1). Overexpression of *TOPORS-AS1* in ovarian cancer cells suppressed cell proliferation and inhibited migration, invasion, and colony formation, and patients with high *TOPORS-AS1* expression had better overall survival compared with low expression ones [257].

Kaler and colleagues assigned a role to the tumor stroma in the interplay between Wnt/ $\beta$ -catenin signaling and  $1,25(\text{OH})_2\text{D}_3$  [258]. They reported that interleukin (IL)-1 $\beta$  secreted by THP-1 macrophages in response to signals coming from the tumor inhibited GSK-3 $\beta$  activity in CRC cells. This resulted in  $\beta$ -catenin stabilization and increased  $\beta$ -catenin/TCF transcriptional activity. Moreover, activation of Wnt/ $\beta$ -catenin signaling in these cells led to stabilization of SNAIL1 and protected them from TRAIL-mediated apoptosis [259]. These authors found that  $1,25(\text{OH})_2\text{D}_3$  repressed the expression of IL-1 $\beta$  in THP-1 macrophages, thus blocking activation of the Wnt/ $\beta$ -catenin pathway in tumor cells and sensitizing them to TRAIL-mediated apoptosis [258,259].

Notably, Meyer and colleagues analyzed the overlap between  $\beta$ -catenin/TCF and VDR/RXR cistromes in CRC cells and found that the two heterodimers colocalize at 74 sites that lie near a limited set of genes including those of *FOS* and *MYC* proto-oncogenes. These data suggest possible transcriptional antagonism of both complexes at certain gene loci [260]. In fact, *MYC* plays a pivotal role in the cross-talk between  $1,25(\text{OH})_2\text{D}_3$  and the Wnt/ $\beta$ -catenin pathway. On the one hand, ligand-activated VDR inhibits *MYC* expression by direct interaction with two VDREs in the promoter region [260,261]. On the other hand, the antagonism of  $1,25(\text{OH})_2\text{D}_3$  on Wnt/ $\beta$ -catenin signaling prevents the transcription of *MYC* mediated by  $\beta$ -catenin/TCF through several Wnt-responsive elements (WRE) at the *MYC* promoter [148,262].

#### 4.1.5 Wnt/ $\beta$ -catenin antagonism by $1,25(\text{OH})_2\text{D}_3$ in animal models and clinical trials

Several studies using animal models to establish the protective action of  $1,25(\text{OH})_2\text{D}_3$  and nonhypercalcemic analogs on CRC have assessed the status of the Wnt/ $\beta$ -catenin pathway. Most, if not all, of these studies confirmed an antagonistic action on this pathway. A clinical trial conducted by Ahearn and colleagues was designed to study the effect of 6 months of daily supplementation with vitamin D<sub>3</sub> (800 IU) and/or calcium (2 g) on the expression of the Wnt/ $\beta$ -catenin pathway proteins APC,  $\beta$ -catenin, and E-cadherin in crypts of normal rectal mucosa from patients with sporadic colorectal adenoma [263]. Both vitamin D<sub>3</sub> and calcium individually

increased the expression of APC and reduced that of  $\beta$ -catenin in the differentiated upper half of the crypts, which resulted in a higher APC/ $\beta$ -catenin ratio. Moreover, supplementation with vitamin D<sub>3</sub> also led to an increase in E-cadherin [263]. These results were mostly confirmed in a subsequent 1-year follow-up clinical trial using daily supplementation with vitamin D<sub>3</sub> (1000 IU) and/or calcium (1.2 g) [264]. In line with this, Juniku-Shkololli and colleagues showed that the average vitamin D levels in CRC patients with positive nuclear  $\beta$ -catenin were lower than those of patients with negative nuclear  $\beta$ -catenin [265]. Altogether, these results confirm those obtained in culture cells and animal models and support the hypothesis that 1,25(OH)<sub>2</sub>D<sub>3</sub> affects Wnt/ $\beta$ -catenin signaling in a way that is protective in CRC. Interestingly, a study has shown that in 67 CRC patients, high circulating 25(OH)D<sub>3</sub> levels associate with low promoter methylation of the extracellular Wnt inhibitor *SFRP2* gene, suggesting that vitamin D might also antagonize the Wnt/ $\beta$ -catenin pathway through epigenetic mechanisms [266]. In another study, the RNA expression levels of VDR and Wnt-inhibitory factor (WIF)1 correlated directly and were found low in CRC tissues in comparison with their marginal tissues [267]. Curiously, stabilization of  $\beta$ -catenin protein expands mast cells to promote high incidence of colon polypoidosis in mice [268]. This suggests an indirect contribution of  $\beta$ -catenin signaling in mast cells to their maturation and to increased risk of CRC.

#### 4.1.6 Antagonism of 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR by the Wnt/ $\beta$ -catenin pathway

In addition to 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibition of the Wnt/ $\beta$ -catenin pathway, there is also evidence of a bidirectional cross-talk, and thus, that Wnt/ $\beta$ -catenin signaling may also interfere the actions of 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR. A mechanism by which Wnt/ $\beta$ -catenin prevents 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR-mediated effects is the induction of the EMT transcription factors SNAIL1 and SNAIL2. Both are phosphorylation targets of GSK-3 $\beta$ , which tags them for  $\beta$ -TrCP-mediated ubiquitination and subsequent proteasomal degradation [248,269,270]. Therefore, Wnt-induced inhibition of GSK-3 $\beta$  results in stabilization of SNAIL proteins. On top of that, inactivation of GSK-3 $\beta$  also induces *SNAIL1* transcription through a mechanism that involves NF- $\kappa$ B [271]. Moreover, the product of the  $\beta$ -catenin/TCF target gene *AXIN2* promotes SNAIL1 stabilization at least in breast cancer cells by controlling GSK-3 $\beta$  localization. When levels of Axin2 increase, GSK-3 $\beta$  is excluded from the nucleus and Snail1 remains in a nonphosphorylated, transcriptionally active state [272]. Additionally, Wu and colleagues have reported that Wnt3A upregulates *SNAIL2* gene expression in breast cancer cells [273]. SNAIL proteins are important negative regulators of

VDR expression, and their regulation by Wnt/ $\beta$ -catenin signaling may be instrumental for the control of 1,25(OH)<sub>2</sub>D<sub>3</sub> actions.

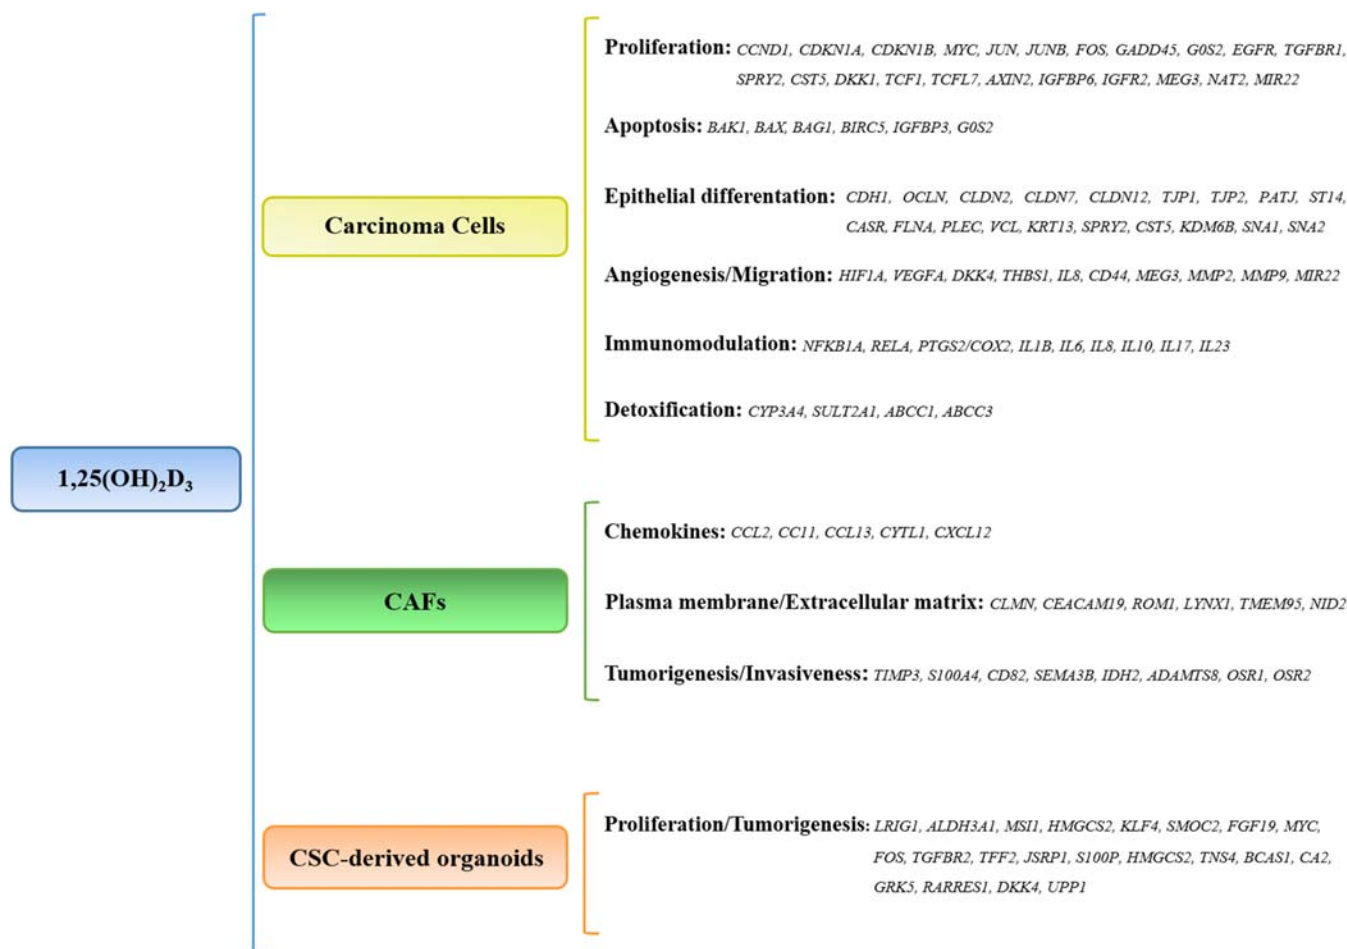

As said before, Wang and colleagues have reported that *miR-372/373* overexpression results in reduced expression of VDR RNA and protein in CRC cells [188]. This *miR-372/373* cluster is a transcriptional target of canonical Wnt signaling harboring three  $\beta$ -catenin/TCF-binding sites in its promoter region [274] and, as expected, is dysregulated in CRC probably due to aberrant activation of the pathway [275,276]. Overexpression of *miR-372/373* potentiates the stemness of CRC cells and promotes self-renewal, chemotherapy resistance, and invasive potential by upregulating stemness-related pathways (e.g., Nanog, Hedgehog) and by downregulating differentiation-associated pathways (e.g., NF- $\kappa$ B, MAPK/ERK) [188]. Altogether, these data suggest that Wnt/ $\beta$ -catenin signaling inhibits VDR expression through the induction of the *miR-372/373* cluster, which contributes to the maintenance of the cancer stem cell phenotype in CRC cells.

## 4.2 Effects on colon cancer cell proliferation, survival, and differentiation

### 4.2.1 Cell proliferation

Similar to the results found in many other cell systems, 1,25(OH)<sub>2</sub>D<sub>3</sub>, 25(OH)D<sub>3</sub>, and several less calcemic 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs inhibit the proliferation of cultured colon carcinoma cells irrespective of *TP53* status, provided that they express sufficient VDR levels [148,277]. Calcipotriol showed a similar antiproliferative effect than 1,25(OH)<sub>2</sub>D<sub>3</sub>, but more efficacy than 20-hydroxyvitamin D<sub>3</sub> [137], while EB1089 induces a higher growth arrest than 1,25(OH)<sub>2</sub>D<sub>3</sub> [278]. Recently, new low-calcemic vitamin D derivatives showed higher antiproliferative effects in HT29 cells than 1,25(OH)<sub>2</sub>D<sub>3</sub> and increased the cell growth-inhibitory effect of 5-fluorouracil (5-FU) on HT29 cells [279]. 1,25(OH)<sub>2</sub>D<sub>3</sub> induces cell cycle arrest at G<sub>0</sub>/G<sub>1</sub> by regulating the phosphorylation of the retinoblastoma protein through the downregulation of cyclin-dependent kinases (CDKs) and the upregulation of the CDK inhibitors p21<sup>CIP</sup> and p27<sup>KIP1</sup> [280–282] (Fig. 89.2).

A major antiproliferative mechanism of 1,25(OH)<sub>2</sub>D<sub>3</sub> in colon carcinoma cells is the repression of the *MYC* oncogene, as almost all human CRCs show a *MYC*-induced transcriptional program [27]. 1,25(OH)<sub>2</sub>D<sub>3</sub> downregulates *MYC* by both direct and indirect mechanisms. As mentioned before, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits *MYC* expression directly by VDR binding to vitamin D response elements localized in its promoter and intragenic regions [261]. In addition, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits *MYC* expression indirectly by the antagonism of

**FIGURE 89.2** 1,25(OH)<sub>2</sub>D<sub>3</sub> controls a large number of genes (GeneCards symbols, [www.genecards.org](http://www.genecards.org)) in human colon carcinoma cells, CAFs, and CSC-derived organoids that are involved in crucial cancer processes.

Wnt/ $\beta$ -catenin pathway at least in part via RhoA-ROCK activation [148,221] and the induction of *CST5* gene encoding cystatin D, an inhibitor of endosomal cysteine proteases of the cathepsin family that localizes partially in the nucleus regulating several target genes [222,283]. Moreover, in other types of cancer cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> also induces the MYC antagonist MAD/MXD1 [284] and increases the interaction of FBW7 E3 ubiquitin ligase with VDR and MYC promoting MYC protein degradation [285].

Several other antiproliferative effects of vitamin D have been reported. 1,25(OH)<sub>2</sub>D<sub>3</sub> induces the expression of the multifunctional growth arrest and DNA damage 45 $\alpha$  (*GADD45A*) gene and *G0S2* [286–288] and regulates many other genes related to proliferation including the AP-1 components *FOS* and *JUN* [148,260,286]. In CRC cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> upregulates the expression of maternally expressed gene 3 (*MEG3*) encoding a lncRNA that has tumor-suppressive or tumor-promoting activities depending on the type of cancer [289,290]. *MEG3* inhibits CRC cell proliferation and migration by

downregulating *Clusterin*, while 1,25(OH)<sub>2</sub>D<sub>3</sub> induces direct binding of VDR to *MEG3* promoter, suggesting that *MEG3* lncRNA is involved in the antiproliferative action of 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC cells [291]. Moreover, vitamin D nanoemulsion (NVD) induces growth arrest at G<sub>2</sub>-phase and apoptosis and inhibits colony formation of HCT116 and HT29 CRC cells. At the protein level, treatment with NVD decreased expression of  $\beta$ -catenin, AKT, and survivin [292]. N-acetyltransferase 2 (*NAT2*) is another gene involved in the antiproliferative action of vitamin D. Thus, *NAT2* inhibits CRC cells proliferation and migration and is transcriptionally upregulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> [293]. Notably, *NAT2* is repressed in CRC patients, and lower expression of *NAT2* correlates with high metastasis risk and poor patient survival.

1,25(OH)<sub>2</sub>D<sub>3</sub> also inhibits the proliferation of human colon carcinoma cells by interfering with growth factor receptor-activated pathways. Epidermal growth factor receptor (EGFR) signaling is recognized as an important player in CRC initiation and progression and is required for efficient tumorigenesis in experimental models

[294,295]. Mutual modulation between ligand-activated VDR and EGFR has been proposed in colonic tumorigenesis and in other tissues [296,297]. In CRC cells, 1,25(OH)<sub>2</sub>D<sub>3</sub> reduces EGFR expression and promotes its ligand-induced internalization [298], and it also diminishes EGFR activity through the induction of E-cadherin expression [148,299] and the repression of *SPRY2* gene [223,300], which are, respectively, negative and positive EGFR regulators [299,301]. Besides, inhibition of the renin–angiotensin system by 1,25(OH)<sub>2</sub>D<sub>3</sub> has been proposed to mediate the antagonism of EGFR signaling in colitis-associated CRC [170]. Conversely, SNAIL1 and several cytokines may mediate the downregulation of VDR by activated EGFR [168,170].

1,25(OH)<sub>2</sub>D<sub>3</sub> interferes the insulin-like growth factor (IGF) pathway. IGF-II is overexpressed in CRC and acts as a mitogen and a survival agent [302]. In contrast, multidrug-resistant and metastatic CRC cells express low levels of IGF-binding protein (IGFBP)-6, and levels are lower in metastatic cells than in nonmetastatic cells, which suggests an antitumorigenic effect [303]. Interestingly, 1,25(OH)<sub>2</sub>D<sub>3</sub> and certain analogs inhibit IGF-II secretion and increase IGFBP-6 levels [304,305]. In addition, 1,25(OH)<sub>2</sub>D<sub>3</sub> induces type II IGF receptor (IGFR-II), which accelerates IGF-II degradation and downregulates this pathway [306].

TGF- $\beta$  inhibits the growth of normal colon epithelial cells [306], and accordingly, alterations in TGF- $\beta$  signaling promote CRC cell growth, migration, invasion, angiogenesis, and metastasis. 1,25(OH)<sub>2</sub>D<sub>3</sub> induces the expression of type I TGF- $\beta$  receptor, which sensitizes CRC cells to the growth-inhibitory action of TGF- $\beta$  [286,306]. Moreover, SMAD3, a downstream protein in the TGF- $\beta$  signaling pathway, binds to SRC-1 and acts as a coactivator of VDR in the induction of 1,25(OH)<sub>2</sub>D<sub>3</sub> target genes [307].

Another indirect mechanism of the antiproliferative effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> is the regulation of miRs. In a cohort of CRC patients, we found that *miR-22* expression is inhibited in 78% of tumor samples compared with adjacent healthy samples and is associated with CRC progression, metastasis, and relapse. Interestingly, 1,25(OH)<sub>2</sub>D<sub>3</sub> upregulates *miR-22*, and transfection of *miR-22* antagonist suppresses the antiproliferative effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> in HCT116 and SW480-ADH cells, showing that *miR-22* contributes to the antiproliferative effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> [308]. *miR-22* inhibits the proliferation and also the invasion and metastatic ability via SNAIL inhibition of CRC cells and of other cancer cell types [308–311]. Curiously, a negative feedback loop exists between *miR-22* and Sp1: while *miR-22* targets Sp1 and suppresses its activation of PTEN/AKT pathway, Sp1 binds to the promoter of *miR-22* repressing its transcription [312]. Another miRNA involved in the antiproliferative effect of vitamin D compounds is *miR-1278*,

which sensitizes CRC cells to 1,25(OH)<sub>2</sub>D<sub>3</sub> by suppressing the expression of CYP24A1 [313].

#### 4.2.2 Cell survival

The fate of cells is largely determined by the level and balance between apoptosis and autophagy. Remarkably, vitamin D has wide regulatory actions on these two processes in many cell systems.

1,25(OH)<sub>2</sub>D<sub>3</sub> plays a role in CRC cell survival by regulating genes involved in apoptosis [278,314,315] (Fig. 89.2). Thus, 1,25(OH)<sub>2</sub>D<sub>3</sub> upregulates the expression of the proapoptotic protein BAK1 and promotes redistribution of the antiapoptotic protein BAG1 from the nucleus to the cytoplasm [278,316]. Furthermore, 1,25(OH)<sub>2</sub>D<sub>3</sub> increases the level of G0S2 [286], a mitochondrial protein that interacts with BCL2 and induces apoptosis of CRC cells by preventing BCL2 from forming antiapoptotic heterodimers with BAX [317]. In a xenograft study, the inhibition of tumor growth by 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs was associated with high level of caspase-3 protein expression, which suggests that 1,25(OH)<sub>2</sub>D<sub>3</sub> induces apoptosis in malignant cells in vivo [318]. In addition, 1,25(OH)<sub>2</sub>D<sub>3</sub> promotes CRC cell sensitivity to the chemotherapeutic agent 5-FU by downregulating the expression of both the antiapoptotic protein survivin and thymidylate synthase, an enzyme involved in DNA de novo synthesis that is the molecular target of 5-FU [319]. 1,25(OH)<sub>2</sub>D<sub>3</sub> restored the sensitivity of CRC cells to TRAIL-induced apoptosis by interfering with the release of IL-1 $\beta$  by macrophages in an in vitro model developed to evaluate the cross-talk between tumor-associated macrophages and CRC cells [259]. Moreover, combination of imatinib with PRI-2191, an analog of 1,25(OH)<sub>2</sub>D<sub>3</sub>, reduces stemness-related expression genes in HCT116 cells that were exposed to 5-FU more efficiently than imatinib alone, showing that this combination could be used to prevent recurrence and to compensate for vitamin D deficiency resulting from imatinib treatment [320].

The role of the *TP53* gene in the proapoptotic action of 1,25(OH)<sub>2</sub>D<sub>3</sub> is controversial. Some reports indicate that this action does not require an intact *TP53* [278,321]. However, the study by Stambolsky and colleagues [194] revealed that mutant p53 protein converts 1,25(OH)<sub>2</sub>D<sub>3</sub> into an antiapoptotic agent. This suggests that the effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on apoptosis is dependent on the *TP53* status of cancer cells. Of note, 1,25(OH)<sub>2</sub>D<sub>3</sub> and metformin have additive/synergistic antiproliferative and proapoptotic effects in CRC cell lines and other types of cells, which is modulated but not hampered by *TP53* status [322].

Vitamin D promotes cell death by autophagy in several cancer types as a protective mechanism to eliminate cells with excessive damage ([323] and refs. therein). Accordingly, vitamin D deficiency or lack of

VDR alters the expression of autophagy genes in intestinal tissues of mice and patients with IBD and dysregulates the balance between autophagy and apoptosis in small intestine, colon tissue, and mouse organoids [324,325].

#### 4.2.3 Cell differentiation

A link between the induction of differentiation and apoptosis by  $1,25(\text{OH})_2\text{D}_3$  has been suggested by the occurrence of apoptosis subsequent to the promotion of differentiation [278].  $1,25(\text{OH})_2\text{D}_3$  increases the expression and/or activity of several intestinal brush border enzymes, such as alkaline phosphatase and maltase that are widely considered as differentiation markers, and enhances the formation of microvilli [278,326–329]. It also increases the expression of a plasma membrane calcium ATPase isoform [330] that has been associated with colonic cell differentiation [331]. Moreover,  $1,25(\text{OH})_2\text{D}_3$  promotes epithelial cell differentiation through the upregulation of proteins involved in maintenance of the epithelial adhesive phenotype such as occludin, zonula occludens (ZO)-1 and -2, and claudin-2, -7, and -12 of tight junctions, E-cadherin of adherens junctions, and plectin of hemidesmosomes [224,286,332] (Fig. 89.2). A key action seems to be the induction of *CDH1*/E-cadherin gene transcription, which relies on a rapid signaling pathway triggered by the entry to the cytoplasm of  $\text{Ca}^{2+}$  from the external medium and the subsequent activation of a RhoA-ROCK1-MSK1/2 cascade [148,221]. Given the repressive effect of *SPRY2* on these intercellular adhesion genes and also on regulators of the polarized epithelial phenotype such as *LLGL2*, *PATJ*, and *ST14* [223,300], the downregulation of *SPRY2* seems to be a major contributor to the prodifferentiation action of  $1,25(\text{OH})_2\text{D}_3$ . Another mechanism by which  $1,25(\text{OH})_2\text{D}_3$  promotes epithelial differentiation is the antagonism of the major EMT inducers *SNAIL* and *SNAIL2* genes, probably as a consequence of the cross-inhibition of the Wnt/ $\beta$ -catenin, TGF- $\beta$ , and EGF pathways ([333] and refs therein).

$1,25(\text{OH})_2\text{D}_3$  also increases the expression of proteins associated with the actin cytoskeleton and intermediate filaments such as keratin-13, vinculin, and filamin A [148,286]. Filamin A has been implicated in cell motility, adhesion, and invasion [334] and in the regulation of nuclear shape during EMT and DNA double-strand break repair [335,336]. Also, it has been reported that low levels of filamin A are found in CRC and that this downregulation is associated with poor clinical prognosis [337].  $1,25(\text{OH})_2\text{D}_3$  can also induce the calcium sensing receptor (CaSR), a G protein-coupled receptor with a key role in regulating calcium homeostasis, and the proliferation and differentiation of normal colonic epithelium and CRC cells [338–342].

$1,25(\text{OH})_2\text{D}_3$  attenuates the effects of TGF- $\beta_1/\beta_2$  on SW480 and HT29 cells, which include an increase in invasion and migration, expression of EMT-related transcription factors and F-actin, and secretion of matrix metalloproteinases (MMP)-2 and -9 [343].

In summary, there are several mechanisms by which  $1,25(\text{OH})_2\text{D}_3$  inhibits the EMT process, which contributes to the promotion of epithelial cell differentiation [344].

### 4.3 Antiangiogenic, antiinflammatory, immunomodulatory, and detoxifying effects

#### 4.3.1 Angiogenesis

The role of  $1,25(\text{OH})_2\text{D}_3$  on the angiogenic capacity of CRC cells relies to a great extent on its ability to suppress the expression and activity of hypoxia-inducible factor (HIF)- $1\alpha$ , a key transcription factor in hypoxia-induced angiogenesis [345]. In a study using prostate cancer cell xenografts,  $1,25(\text{OH})_2\text{D}_3$  decreased the proliferation of tumor-derived endothelial cells in wild-type but not in *Vdr*<sup>-/-</sup> mice, which showed increased vasculature and higher Hif- $1\alpha$  and vascular endothelial growth factor (VEGF) levels [346] (Fig. 89.2). Also, in colitis animal models, vitamin D suppresses HIF- $1\alpha$  overexpression in colonic epithelial cells through the inhibition of NF- $\kappa\text{B}$  pathway [347]. In SW480-ADH CRC cells,  $1,25(\text{OH})_2\text{D}_3$  regulates the expression of VEGF-A and thrombospondin-1, two major opposing factors that control tumor angiogenesis [348]. In addition, prolonged administration of  $1,25(\text{OH})_2\text{D}_3$  to Wistar rats inhibits the development of azoxymethane (AOM)-induced colon tumors in association with a decrease in VEGF expression and vessel counts [349].  $1,25(\text{OH})_2\text{D}_3$  strongly represses DKK4, a weak Wnt antagonist that promotes invasion and angiogenesis in cultured CRC cells and is upregulated in human CRC [241].

#### 4.3.2 Inflammation and immunomodulation

Chronic inflammation is associated with abnormal immune response and may be caused by a variety of factors including bacterial and viral infections and chemical irritants. A considerable amount of evidence suggests that chronic inflammation can predispose to cancer. In particular, the association between chronic IBDs and the increased risk of CRC is well documented [5,350]. Common events in the inflammatory process such as inflammatory cell infiltration and increased expression of proinflammatory cytokines seem to be involved in sporadic and heritable CRC [350]. An antiinflammatory action of vitamin D and a link between vitamin D deficiency and the incidence of IBD have been proposed. The mechanisms by which vitamin D affects inflammation-related CRC include the inhibition of

NF- $\kappa$ B pathway, prostaglandin (PG)-endoperoxide synthase (PTGS-2, also known as COX-2), and several cytokines (Fig. 89.2).

Patients with UC or CD show reduced levels of VDR in intestinal epithelium. Likewise, overexpression of Vdr in experimental models inhibits the colitis-associated increase in proinflammatory cytokines such as TNF, IL-1, and CCL2 and protects mice from developing colitis [351]. In addition, Ananthakrishnan and colleagues proposed that higher predicted plasma 25(OH)D levels significantly reduce the risk of CD [352]. In a study of two cohorts including 798 CRC patients, a high level of circulating 25(OH)D<sub>3</sub> is inversely associated with IL-6 level at diagnosis and with the summary inflammatory *z*-score at diagnosis, at 6 months after diagnosis and over the course of 2 years. Moreover, 25(OH)D<sub>3</sub> level was inversely associated with that of IL-10 over this period [353]. In another study with 117 CRC patients, serum 25(OH)D levels inversely correlated with several systemic inflammatory markers such as blood neutrophil count, serum C reactive protein, blood neutrophil/lymphocyte ratio, and serum IL-6 levels, but not with diagnosis, while the lowest serum levels associated with mismatch repair deficiency, serrate morphology, and high body mass index [354].

A definitive demonstration of a protective role of vitamin D compounds in IBD patients has not been fully demonstrated, as some studies on the effect of vitamin D supplementation on inflammatory markers in patients with colorectal adenomas showed inconclusive results. Thus, the generation of intestine-specific and myeloid-specific *Vdr*<sup>-/-</sup> mice in a dextran sulfate sodium (DSS) model of experimental colitis showed that *Vdr* inactivation in macrophages and granulocytes mildly affected colitis-associated symptoms and increased proinflammatory cytokines and  $\beta$ -defensin-1 in colon *descendens* of mice with colitis and in inflamed colon [355]. On the contrary, loss of *Vdr* in the intestine did not change colitis-associated symptoms or mucosal cytokine expression. Hodge and colleagues have reported that 1-year treatment with vitamin D (1000 IU/d) and calcium (1.2 mg/d) alone or in combination failed to affect the expression in the rectal mucosa of TLR-4/5 and phospho-IKK $\alpha$ / $\beta$ , two biomarkers of inflammation, in a subset of 105 participants from a colon adenoma recurrence chemoprevention clinical trial [356]. Moreover, Protiva and colleagues showed that supplementation of a Western diet with 1,25(OH)<sub>2</sub>D<sub>3</sub> increased the expression of genes involved in inflammation in human colon, an effect that was reversed by calcium supplementation [357].

VDR is expressed by almost all cell types of the immune system, and accordingly, a large number of studies support a key immunomodulatory role of 1,25(OH)<sub>2</sub>D<sub>3</sub> [358–360]. Many times, 1,25(OH)<sub>2</sub>D<sub>3</sub> has

been considered an enhancer of the innate immune system against infections and tumor cells by activating the responsive cells (macrophages, neutrophils), and a repressor of the adaptive immune reactions by deactivating dendritic cells and CD4<sup>+</sup> type 1 helper T (Th1) cell responses (production of interferon- $\gamma$ , IL-1, IL-6, IL-12) and promoting Th2 and Treg cell responses (production of IL-10, IL-4, IL-5), which, in contrast, could potentially reduce the protection against tumors. However, this inhibitory effect on the proinflammatory Th1 response has been observed in experimental settings following overstimulation of the cells. Moreover, the long-term consideration that the induction of IL-10 by VDR ligands has only protumoral consequences is unclear, as IL-10 seems to have a dual effect in cancer also promoting tumor-specific T cell immune surveillance and hindering pathogenic inflammation [361]. Thus, in line with its selection during evolution, vitamin D has probably the essential action of a regulator, which is potentiating the early defensive proinflammatory activity of the immune system against infections and tumors and inhibiting at later stages the overactivation and self-reactivity to prevent adverse consequences such as chronic inflammation or autoimmunity [362–364].

Gut epithelial VDR is important to protect the intestinal barrier integrity and regulates the gut innate immunity. In mice, mucosal inflammation is controlled by gut epithelial Vdr signaling by suppressing epithelial cell apoptosis [365]. 1,25(OH)<sub>2</sub>D<sub>3</sub> signaling is required for colonic group 3 innate lymphoid cells (ILC3)–mediated innate immunity against *Citrobacter rodentium* (*C. rodentium*) through regulation of cell proliferation [366]. Besides, mice with depleted Vdr expression show a more severe clinical colitis and stronger Th1 and Th7 responses than control mice, with enhanced mucosal inflammatory responses in the gut.

COX-2 synthesizes PGs from arachidonic acid and other fatty acids. PGs are mediators of inflammatory processes and regulate the proliferation, apoptosis, angiogenesis, and other parameters of several types of cancer cells [367,368]. Moreover, PGs, such as PGE<sub>2</sub>, stimulate CRC cell proliferation, and COX-2 is overexpressed in CRC patients [369]. A large number of epidemiological studies using aspirin and other COX inhibitors support the benefit of COX-2 inhibition for CRC patients [367,370]. Although 1,25(OH)<sub>2</sub>D<sub>3</sub> reduces the protumorigenic effect of PGE<sub>2</sub> in prostate cancer cells by inhibiting COX-2 and decreasing levels of PGE<sub>2</sub> and two PG receptors (EP2 and FP) [371], similar effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC cells have not been clearly established. In chemically induced CRC models, treatment with vitamin D or some analogs reduced COX-2 expression [372,373]. An indirect mechanism to control the production of PGE<sub>2</sub> by 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC cells

could be mediated by the activation of CaSR, as this inhibits phospholipase A2 activity and thus reduces the amount of arachidonic acid available for PG synthesis [374]. Importantly, vitamin D and calcium favorably modulate the balance of expression of COX-2 and 15-hydroxyPG dehydrogenase, its physiological antagonist, in the normal-appearing colorectal mucosa of patients with colorectal adenoma [375].

NF- $\kappa$ B is a protein complex that controls the transcription of many genes, including a large number of those responsible for cytokine production and cell survival. NF- $\kappa$ B is present in all cell types and is a key regulator of immune responses and inflammation. Improper regulation of NF- $\kappa$ B has been linked to cancer, inflammatory, and autoimmune diseases [367,376]. In unstimulated cells, NF- $\kappa$ B is in an inactive state sequestered in the cytoplasm by a family of inhibitors, called inhibitors of  $\kappa$ B (I $\kappa$ B). Upon stimulation by proinflammatory cytokines, NF- $\kappa$ B translocates from the cytosol to the cell nucleus, where it stimulates the transcription of genes involved in proinflammatory processes, such as IL-6, IL-8, TNF- $\alpha$ , and COX-2 [367]. In CRC cells, NF- $\kappa$ B activity is inhibited by 1,25(OH) $_2$ D $_3$  through different mechanisms, including inactivation of the p65 subunit of the NF- $\kappa$ B complex, thus preventing the binding of NF- $\kappa$ B to DNA [377], and increasing the expression of the inhibitor subunit I $\kappa$ B [376–379]. Moreover, CRC cells treated with an antagonist of VDR showed increased NF- $\kappa$ B activity and reduced I $\kappa$ B expression [380]. Accordingly, high dietary vitamin D decreases NF- $\kappa$ B activation, and thereby reduces inflammation in mouse colonic epithelial cells [381], and *Vdr* $^{-/-}$  mice exhibit a proinflammatory phenotype associated with increased NF- $\kappa$ B activity in the intestine [382]. Thus, 1,25(OH) $_2$ D $_3$  exerts antiinflammatory properties and inhibits IL-1 $\beta$ , IL-6, IL-8, TNF- $\alpha$ , and possibly other cytokines (for example, IL-17, IL-12, and TGF- $\beta$ ), which are expressed at high levels in CRC patients and may be involved in CRC progression [383–385]. This effect of 1,25(OH) $_2$ D $_3$  relies at least in part on the blockade of NF- $\kappa$ B [376–379].

In contrast to the antiinflammatory and immunomodulatory role proposed for vitamin D in CRC, it has been suggested that low levels of 25(OH)D or low VDR expression in CRC patients might be a consequence of chronic inflammation or of infection rather than the cause [386]. Some studies support this reverse causality idea, showing that the presence of proinflammatory cytokines might impair 1,25(OH) $_2$ D $_3$  synthesis limiting its antiinflammatory action in CRC cells [387]. Probably, mutual regulation exists between vitamin D status and inflammation, and the result in each situation will depend on the relative intensity of the respective signals. Supporting this idea, the transcriptional response to vitamin D is impaired in COVID-19 patients who have

a strong proinflammatory Th1 cell phenotype, which leads to a failure to switch to IL-10 production and inflammatory resolution [388].

In summary, there is overwhelming evidence from experimental in vitro and in vivo studies indicating a homeostatic role of vitamin D on the biology of many types of cells and reactions of the immune system in a large series of systems and contexts including the protection against CRC. As said by Martens and colleagues in an excellent review, although the translation of these observations to the clinic is still pending, it seems clear the convenience of avoiding vitamin D deficiency to maintain a fully functional immune system [364].

#### 4.3.3 Microbiome

An increasing interest in the role of the microbiome in human health and disease including CRC has boosted the number of studies on vitamin D and the gut microbiome [74,389–391]. A mutual interaction exists between vitamin D and the intestinal microbiome that is connected to CRC. Thus, there is a link between alteration of the gut microbiome, known as dysbiosis, and CRC. Vitamin D affects the gut microbiota composition and activity as shown by the effect of vitamin D deficiency promoting gut permeability, colon mucosa bacterial infiltration, and translocation of intestinal pathogens leading to gut inflammation [390–392]. As bacteria lack VDR, the effect of vitamin D is mediated by the host, to a great extent via the regulation of the epithelial barrier and immune system.

*Fusobacterium nucleatum* (Fn) has been associated with CRC. *FadA*, a virulence factor identified from Fn, binds E-cadherin, activates  $\beta$ -catenin signaling, and regulates the inflammatory and oncogenic responses [393]. *Vdr* $^{-/-}$  mice develop dysbiosis and display lower expression of E-cadherin in gut epithelial and immune cells, fewer tolerogenic dendritic cells, and intensified gut inflammation compared with wild-type (wt) mice, leading to higher susceptibility to damage in the gut [394]. In line with this, vitamin D-deficient mice that were given 2% of DSS displayed a pronounced epithelial barrier dysfunction, were more susceptible to adherent-invasive *Escherichia coli* colonization, and showed aggravated colonic injury [395]. Also, in agreement, fecal samples from *Vdr* $^{-/-}$  mice revealed changes in fecal microbiomes showing that *Vdr* affects different pathways such as nucleotide-binding oligomerization domain-like receptor, signal transduction, detoxification, amino acid synthesis, infections, cancer, and other diseases [396]. *Vdr* $^{-/-}$  mice had also fewer *C. rodentium* in the feces and more I1-22 producing innate lymphoid cells, and less antibacterial peptides than wt mice. Treatment of *Vdr* $^{-/-}$  mice with antibiotics reversed colonization resistance to *C. rodentium* infection, and transferring the microbiota of *Vdr* $^{-/-}$  to wt germ-free mice

resulted in colonization resistance [397]. Moreover, lower level of vitamin D in CD1 mice reduced the expression of Vdr and increased that of proinflammatory genes in the colon, and it causes lower numbers of colonic *Bacterioides/Prevotella* and higher serum lipopolysaccharides (LPS) concentration [398]. Furthermore, prebiotics but not probiotics affect the transformation of 2-amino-3-methylimidazo[4,5-f] quinoline (IQ) to 2-amino-3,6-dihydro-3-methyl-7H-imidazo[4,5-f]quinoline-7-one (7-OH-IQ) by fecal microbiota [399], showing that microbiota can also regulate the response to carcinogens [400]. Notably, while regulation of the Vdr is a common mechanism used in the host defense against pathogens, some microorganisms such as *Mycobacterium tuberculosis*, *Mycobacterium leprae*, *Aspergillus fumigatus*, Epstein–Barr virus, and HIV have been shown to decrease innate immune defense by repressing Vdr [386].

Several studies support these findings. He and colleagues reported that gut epithelial Vdr regulates microbiome-dependent mucosal inflammation by suppressing intestinal cell apoptosis [365]. In an experimental model of IBD, Cantorna and colleagues showed that vitamin D–deficient mice presented a reduced frequency of FoxP3<sup>+</sup> and RorγT/FoxP3<sup>+</sup> Treg cell population in the colon. Germ-free recipients of vitamin D–sufficient mice microbiota had more RorγT/FoxP3<sup>+</sup> Treg cells than those of vitamin D-deficient mice microbiota. Higher frequency of the RorγT/FoxP3<sup>+</sup> Treg cell population in vitamin D sufficiency colon correlated with higher amount of *Clostridium XIVa* and *Bacteroides* in vitamin D–sufficient compared with vitamin D–deficient cecum. Also, vitamin D–deficient mice with fewer RorγT/FoxP3<sup>+</sup> Treg cells were more susceptible to colitis than vitamin D–sufficient mice. The authors indicated that early vitamin D status modulates the microbiota to optimize the population of colonic RorγT/FoxP3<sup>+</sup> Treg cells that are important for resistance to colitis [401]. In a randomized clinical trial, no differences were found in microbiome α-diversity between vitamin D and placebo groups at baseline and follow-up on the effect of vitamin D on fecal microbiota of overweight or obese otherwise healthy adults. However, there was an association between community composition and vitamin D supplementation at the genus level (*Lachnospira*, *Blautia*, *Coproccoccus*, *Ruminococcus*), indicating effects on fecal microbiota [402].

A model of AOM/DSS-induced CRC in intestinal conditional *Vdr*<sup>−/−</sup> (*Vdr*<sup>ΔIEC</sup>) mice showed that *Vdr* deficiency changes bacterial profile from normal to carcinogenesis susceptibility. Fecal samples from this mice model produced an activation of STAT3 signaling in human and mouse organoids. Vdr protein bound to the *Jak2* promoter, while lack of Vdr increased *Jak2* function in response to intestinal dysbiosis, and the microbiome-

induced activation of Stat3 was diminished by an inhibitor of Jak/Stat [403]. Moreover, HCT116 cells treated with conditioned medium (CM) from probiotic lactic acid bacteria (LAB) showed increased expression of VDR and of its target *CAMP* gene encoding cathelicidin. Two probiotic proteins, P40 and P75, present in the LAB-CM increased VDR in organoids and protected them from the inflammatory response induce by TNF-α [404]. Importantly, genome-wide association analysis of the gut microbiome in two large cohorts of individuals has identified VDR as a factor influencing the gut microbiota [405].

#### 4.3.4 Detoxification

The gastrointestinal tract and liver are the main organs responsible for drug metabolism. They play key roles in the defense against toxins and other xenobiotics in the diet that may contribute to CRC development [406]. The biotransformation process, often referred to as a detoxification process, involves two distinct stages. Phase I reactions include the introduction of polar functional groups into the molecule or modification by oxidation, reduction, or hydrolysis. Phase II reactions comprise chemical conjugations to water-soluble molecules. These reactions are carried out by a large number of enzymes, including the CYP450 family and sulfotransferases among others.

1,25(OH)<sub>2</sub>D<sub>3</sub> has an impact on the detoxification process by regulating the expression of some of these enzymes in the intestine [407] (Fig. 89.2). The best example is CYP3A4, which is considered the most important human drug-metabolizing enzyme and is induced by 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC cells [408]. In addition, SULT2A1 (a phase II sulfotransferase) and members of the multidrug resistance–associated protein (MRP) family are also induced by 1,25(OH)<sub>2</sub>D<sub>3</sub> in CRC cells [409,410]. Recently, SULT2A1 showed sulfating activity on all vitamin D<sub>3</sub>–related compounds, SULT1A1 just for 1,25(OH)<sub>2</sub>D<sub>3</sub> and SULT2B1a/SULT2B1b for 7-dehydrocholesterol [411]. However, SULT2B1b overexpression in CRC promotes cell growth and invasion in vitro, and accordingly, high SULT2B1b is an unfavorable prognosis indicator [412].

CYP3A4, SULT2A1, and MRP3 are involved in the elimination of the secondary bile acid LCA, which induces DNA damage and inhibits DNA repair enzymes in colonic cells. Accordingly, LCA promotes CRC in experimental animals, and high levels of LCA have been found in CRC patients [413]. Since VDR functions as a receptor for LCA [414] and the activation of VDR by LCA induces CYP3A4, SULT2A1, and MRP3 expression, this is a feedback mechanism that results in LCA elimination in the colon. Thus, VDR helps to decrease the level of its agonist, the deleterious secondary bile acid LCA.

Interestingly, a positive correlation between levels of 25(OH)D<sub>3</sub> and total thiol concentration (TTC), a biomarker of antioxidant capacity, has been reported. Thus, there is an inverse association between 25(OH)D and mortality in patients with low or medium TTC, suggesting that survival advantages in CRC patients with adequate vitamin D depend on antioxidant capacity and are most pronounced in cases of low antioxidant capacity [85].

#### 4.4 Effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> in colorectal cancer—associated fibroblasts

Tumor progression depends not only on tumor cells but also on tumor microenvironment or stroma, which comprehends the ECM, surrounding and infiltrating host (stromal) cells in the tumor mass and secreted factors. The interaction of tumor cells with these stromal constituents is crucial at all stages of tumor development [415]. Stromal fibroblasts or CAFs are the cell type most abundant in tumor microenvironment, and a mutual dynamic interaction exists between tumor cells and CAFs [416]. CAFs are heterogeneous, as they can be originated by the phenotypic change (activation) of resident fibroblasts, by the recruitment and activation of bone marrow-derived fibrocytes and mesenchymal stem cells, or by the transdifferentiation of epithelial, endothelial, or smooth muscle cells, adipocytes, or pericytes in response to signals secreted by tumor cells or by other cells of the tumor stroma. Upon recruitment and activation, CAFs can remodel the ECM (volume, composition, and organization), secrete soluble factors that act in a paracrine manner on carcinoma and immune cells, modify tumor metabolism and response to therapy, and induce the recruitment of bone marrow precursors [417]. Thus, CAFs are thought to actively contribute to the tumorigenic process promoting cancer invasion, angiogenesis, and metastasis and inhibiting the immune response [418]. In CRC, CAFs also increase the frequency of tumor-initiating cells [16]. In addition, tumor stroma can function as a barrier that prevents efficient intratumor drug delivery. Accordingly, poor prognosis CRC subtypes are characterized by a prominent desmoplastic reaction and elevated expression of a CAFs-associated gene signature [15,16,419]. These findings led to the idea that combination therapies that target both the stromal and the neoplastic cells may provide therapeutic benefits for cancer patients [418]. However, the role of stromal fibroblasts in tumor progression is complex, as tumor-suppressive effects of these cells have also been described. Thus, treatments directed at reprogramming activated stromal fibroblasts to nonactivated/normal stromal cells may be more effective than

those focused on general depletion of the tumor-associated stroma [418,420–422].

Our group studied the possible effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> on CRC stromal fibroblasts. We established primary cultures of colon normal fibroblasts (NFs) and CAFs, derived from fresh biopsies of CRC patients, and we found that all the primary cultures responded to 1,25(OH)<sub>2</sub>D<sub>3</sub> and expressed VDR. Besides, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits the protumoral action of activated fibroblasts. First, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited the capacity of alter the ECM, tested as its capacity to remodel collagen gels. And second, 1,25(OH)<sub>2</sub>D<sub>3</sub> reduced the ability of CAFs to promote the migration of CRC cells. This showed that 1,25(OH)<sub>2</sub>D<sub>3</sub> reprograms CAFs to a less activated phenotype. VDR expression in these primary cultures correlates with the inhibitory effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on the promigratory effect of fibroblasts on CRC cells, suggesting that this antitumoral action of 1,25(OH)<sub>2</sub>D<sub>3</sub> depends on VDR expression in colon fibroblasts [160]. By microarray analyses, we observed the changes that 1,25(OH)<sub>2</sub>D<sub>3</sub> provokes in the gene expression profile, regulating more than 1000 genes in NFs and CAFs, with a 21% overlap. 1,25(OH)<sub>2</sub>D<sub>3</sub> target genes are involved in cell adhesion, differentiation and migration, tissue remodeling, blood vessel development, and inflammatory response and encoded mainly for ECM components and cytokines (Fig. 89.2). Moreover, we identified a gene signature imposed by 1,25(OH)<sub>2</sub>D<sub>3</sub>, which correlates with a better prognosis of CRC patients from publicly available data sets, showing the clinical relevance of the gene expression effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> in CAFs. Additionally, we studied the VDR expression in a cohort of 658 metastatic CRC patients with prolonged clinical follow-up. High VDR expression in carcinoma cells or in tumor fibroblasts, and particularly in both, was associated with a better OS and disease-free survival independently of its expression in carcinoma cells [160]. Also, multivariate Cox regression analysis showed that VDR expression in tumor stromal fibroblasts is an independent predictor of OS in CRC. Interestingly, the regulation by 1,25(OH)<sub>2</sub>D<sub>3</sub> of CAFs genes encoding cytokines and growth factors suggests that it may also affect in a paracrine manner the biology of carcinoma cells and other cell types in the tumor microenvironment. Accordingly, 1,25(OH)<sub>2</sub>D<sub>3</sub> decreases the amount of *miR-10a-5p* found in the exosomes secreted by human pancreatic CAFs, which attenuates the promigratory and proinvasive effects that these CAFs exert on pancreatic carcinoma cells [423]. Together, all these data indicate that CAFs from CRC patients express VDR and 1,25(OH)<sub>2</sub>D<sub>3</sub> regulates its gene expression, biology, and phenotype. Thus, the anticancer action of 1,25(OH)<sub>2</sub>D<sub>3</sub> on CRC is mediated by its direct action on CRC cells, and also by its modulation of the tumorigenic properties

**FIGURE 89.3**  $1,25(\text{OH})_2\text{D}_3$  protects against CRC acting on carcinoma cells, cancer-associated fibroblasts, and cancer stem cells. It inhibits the proliferation, migration, and invasion capacities of colon carcinoma cells while promoting their differentiated phenotype in part through the interference of the Wnt/ $\beta$ -catenin signaling pathway.  $1,25(\text{OH})_2\text{D}_3$  sensitizes these cells to apoptotic signals and reduces their angiogenic potential, modulates several immune responses, reduces the dysbiosis, and contributes to clear mutagens and xenobiotics. In addition,  $1,25(\text{OH})_2\text{D}_3$  inhibits the protumorigenic effects (migration, invasion) of cancer-associated fibroblasts on carcinoma cells and perhaps other stromal cell types, and acts on cancer stem cells attenuating their proliferation and promoting some differentiation traits.

of CAFs (Fig. 89.3). These results support the possible use of VDR agonist as antistromal agents in CRC and suggest that they may benefit patients even if their carcinoma cells lack VDR provided that CAFs express sufficient VDR level.

Due to the importance of the interference of Wnt/ $\beta$ -catenin signaling by  $1,25(\text{OH})_2\text{D}_3$  in carcinoma cells, we investigated their possible interaction in colon fibroblasts. We chose Wnt3A as a representative Wnt protein since it is one of the best described canonical Wnts. Global transcriptomic studies by RNA-seq analysis of the action of single and combined  $1,25(\text{OH})_2\text{D}_3$  and Wnt3A treatments of the CCD-18Co human colon myofibroblast cell line showed that both agents have additive gene regulatory effects [424]. A higher number of genes were found regulated by the combination of  $1,25(\text{OH})_2\text{D}_3$  and Wnt3A than by the single treatments: 800 genes were common targets of both agents, while 1309 genes were significantly regulated by the

combined treatment but not by the single treatments [424]. The expected additive effect explained 83% of the variability observed in the combined treatment, suggesting that most of these genes are also regulated by the single treatments. Thus, the results of the combined treatment were largely predicted by the sum of the effects of the two single treatments. We also studied the effects of  $1,25(\text{OH})_2\text{D}_3$  and Wnt3A to modulate the phenotype of CCD-18Co myofibroblasts. Regarding their ability to remodel the ECM, we found that while  $1,25(\text{OH})_2\text{D}_3$  inhibited the capacity of CCD-18Co cells to contract collagen gels, Wnt3A had the opposite effect, and the combined treatment reduced the effect of each single treatment. Both  $1,25(\text{OH})_2\text{D}_3$  and Wnt3A reduced the proliferation of CCD-18Co myofibroblasts, and the combined treatment showed an additive effect. Additionally,  $1,25(\text{OH})_2\text{D}_3$  and Wnt3A single treatments inhibited the migration of CCD-18Co cells and IMR90 human lung fibroblasts, and their combination had a

similar effect than the individual treatments [424]. These studies were expanded to patient-derived primary NFs and CAFs. We analyzed in five paired NFs and CAFs cultures the expression of three genes identified in the RNA-seq study (*OSR2*, *OSR1*, and *PGD*) carried out in the CCD-18Co myofibroblasts.  $1,25(\text{OH})_2\text{D}_3$  regulated all these genes in NFs and CAFs except for *PGD* in CAFs that was induced by  $1,25(\text{OH})_2\text{D}_3$  in four out of five primary cultures but did not reach statistical significance. Moreover,  $1,25(\text{OH})_2\text{D}_3$  significantly inhibited the capacity of NFs to contract collagen gels, while the effect of Wnt3A was variable, increasing the contraction of the gels in four patients but having an opposite effect in one. The combined effects of  $1,25(\text{OH})_2\text{D}_3$  and Wnt3A had an intermediate effect between both single treatments [424]. In conclusion,  $1,25(\text{OH})_2\text{D}_3$  and Wnt3A are strong regulators of the gene expression and phenotype of colon fibroblasts. However, in contrast to the antagonism reported in carcinoma cells, they have an additive and partially overlapping effect in fibroblasts [424,425].

Reduced VDR protein is associated with an increased migration of fibroblasts in CD, and treatment with  $1,25(\text{OH})_2\text{D}_3$  led to VDR upregulation and prevented the increase in fibroblast migration. Accordingly, lower collagen deposition and a preserved histological architecture was found in grafts obtained from vitamin D-treated mice compared with vehicle-treated mice [426]. The collagen layer was thicker in vehicle-treated mice than in vitamin D-treated mice, which showed reduced levels of *Col1a1* RNA and protein and of vimentin protein. Vitamin D-treated mice had also reduced *Cd86* and *Il-6* expression [426]. These data suggest that vitamin D reduces murine intestinal fibrosis.

#### 4.5 Effects of $1,25(\text{OH})_2\text{D}_3$ in colorectal stem cells—derived organoids

The Cancer Stem Cell (CSC) theory proposes that tumors initiate, progress, and perhaps become resistant to therapies due to the mutation of tissue resident stem cells (SCs). Intestinal SCs (ISCs) reside at the crypt bottom, and presently the expression at the plasma membrane of *Lgr5* protein is considered their best marker [427]. In concordance with the CSC theory, the deletion of *Apc* gene in *Lgr5*<sup>+</sup> ISC, but not in partially or fully differentiated intestinal cells, leads to the formation of adenomas in mice [428].

These data have prompted studies on the putative effect of vitamin D compounds on SCs and CSCs of several tissues and neoplasias. To this aim, our group faced the analysis of  $1,25(\text{OH})_2\text{D}_3$  action on human colorectal CSC by establishing organoid cultures from patient-derived matched normal and tumor tissue.

Organoids are three-dimensional (3D), self-organized multicellular structures generated by stem cells embedded in an ECM that is covered by a complex tissue-specific serum-free medium containing a mixture of growth factors, vitamins, agents, and inhibitors [429,430]. Although with a series of limitations, organoids recapitulate some of the features of a particular organ or tumor of origin and thus, are today considered a better system to study cancer processes and the activity of agents and drugs than immortalized cell line monolayers grown for decades on plastic dishes and animal models [431–433].

Human colon organoids have been used to study genome wide effects of  $1,25(\text{OH})_2\text{D}_3$ . By RNA-seq and chromatin immunoprecipitation-sequencing (ChIP-seq) assays, our group has shown that  $1,25(\text{OH})_2\text{D}_3$  profoundly and differentially regulates the gene expression profile of six CRC patient-derived matched normal and tumor organoid cultures. In normal organoids, 96 h treatment with  $1,25(\text{OH})_2\text{D}_3$  induced stemness-related genes (*LGR5*, *SMOC2*, *LRIG1*, *MSI1*, *PTK7*, and *MEX3A*), some of which (*SMOC2*, *MSI1*) were identified as direct targets [434]. By contrast, in tumor organoids,  $1,25(\text{OH})_2\text{D}_3$  had only minor effects on stemness genes. Notably, in both normal and tumor organoids,  $1,25(\text{OH})_2\text{D}_3$  reduced cell proliferation and the expression of proliferation and tumorigenesis genes such as *GRK5*, *RARRES1*, *S100P*, *TNS4*, *ALDH3A1*, *BCAS1*, *S100P*, and *SERPINE1* without affecting Wnt target genes, which agrees with the key role of Wnt and Notch pathways as main responsible for intestinal crypt SC stemness (Fig. 89.2). Of note, an exception is the down-regulation by  $1,25(\text{OH})_2\text{D}_3$  in both normal and tumor organoids of *DKK4*, a Wnt target that as said before encodes an inhibitor of Wnt/ $\beta$ -catenin signaling up-regulated in CRC and other neoplasias that has tumor-promoting effects including the induction of chemotherapy resistance [241,244,245,435]. In line with this, gene set enrichment analysis (GSEA) showed an inverse association of the  $1,25(\text{OH})_2\text{D}_3$  profile (RNA-seq) with E2F, mTOR, and MYC proliferative signatures and, contrarily, a significant enrichment in  $1,25(\text{OH})_2\text{D}_3$ -treated tumor organoids of the differentiation signature EPHB2<sup>low</sup> versus EPHB2<sup>high</sup> of human colon cells [434]. Remarkably, electron microscopy analyses revealed the induction by  $1,25(\text{OH})_2\text{D}_3$  of several cell differentiation traits in tumor organoids such as cell-to-cell adhesion structures, chromatin decondensation, and increased cytoplasmic organelle. In another study, we compared the transcriptomic profiles of both types of organoids from colon and rectum, and also found an induction of stemness genes by  $1,25(\text{OH})_2\text{D}_3$  in normal but not in tumor rectum organoids [436]. Together, these data suggest an antitumor action of  $1,25(\text{OH})_2\text{D}_3$  on CRC acting on CSC (Fig. 89.3).

In a later study, Li and colleagues reported the effect of  $1,25(\text{OH})_2\text{D}_3$  on the colon organoids of one healthy individual [437]. The authors used assay for transposase-accessible chromatin sequencing (ATAC-seq) to analyze chromatin accessibility at 4 and 8 h of  $1,25(\text{OH})_2\text{D}_3$  treatment and RNA-seq to assess the transcriptional response to  $1,25(\text{OH})_2\text{D}_3$  at 6 and 24 h posttreatment. Results were mostly concordant with those of Fernández-Barral and colleagues [434] and revealed a high number of target genes (including *LRIG*, *SMOC*, *KLF4*, *GRK5*, *RARRES1*, *BCAS*, *TNS4*, and, interestingly, *FGF19*, *MYC*, *FOS*, and *TGFB2*) involved in a wide array of pathways and processes with a large degree of overlap between the two studies and only few discordances. Likewise, no Wnt/ $\beta$ -catenin target genes other than *MYC* were found as regulated by  $1,25(\text{OH})_2\text{D}_3$ . Notably, the canonical VDR-binding motif was the most abundant at peaks in upregulated genes in both the ChIP-seq [434] and the ATAC-seq assays [437]. In the two studies, chromatin VDR-binding sites and accessible sites following  $1,25(\text{OH})_2\text{D}_3$  treatment were located at promoters and in many cases at distant introns and intergenic regions. More recently, Vaughan-Shaw and colleagues [438] have performed a microarray analysis of the effect of the treatment with 50 nM  $1,25(\text{OH})_2\text{D}_3$  during 24 h of organoids of three CRC patients. The authors found 111 differentially expressed genes, many of them involved in the regulation of cell proliferation, differentiation, adhesion, and migration, with a substantial concordance with data from Fernández-Barral and colleagues [434].

At a smaller scale, human intestinal organoids have been used to confirm the action of  $1,25(\text{OH})_2\text{D}_3$  on particular genes. Thus, Bhasin and colleagues reported the upregulation by  $1,25(\text{OH})_2\text{D}_3$  of the uridine phosphatase 1 (*UPP1*) gene, which leads to a reduction of uridine-induced DNA damage in patient-derived CRC organoids [439]. Another study has reported that MDL-811, an allosteric activator of the nicotinamide adenine dinucleotide-dependent deacetylase sirtuin (*SIRT6*), increases histone H3 deacetylation at the *CYP24A1* gene locus. MDL-811 reduces cell proliferation in CRC cell lines and patient-derived organoids and has a synergistic anti-CRC effect in combination with vitamin D in *Apc<sup>min/+</sup>* mice [440]. In addition, the induction by  $1,25(\text{OH})_2\text{D}_3$  of genes involved in the cellular homeostasis of divalent cations (calcium, manganese) previously identified in mice (*TRPV6*, *SLC30A10*, *ATP2B1*) has been confirmed in human duodenal organoids [441].

Mouse organoids have also been used to study vitamin D action on the intestine. Work performed in intestinal organoids from wild-type and mutant *Vdr* mice revealed the regulatory action of vitamin D on the balance between autophagy and apoptosis promoting cell

survival through Atg16l1 and Beclin-1 [325]. Likewise, work in mouse intestinal organoids confirmed the protective effect of vitamin D against injury by restoring the expression of tight junction Zo-1 and claudin 2 proteins that are crucial for intestine barrier function [442]. Contrarily to data in human colon and rectum organoids, a study has reported that  $1,25(\text{OH})_2\text{D}_3$  suppresses cell stemness and proliferation in mouse small intestine organoids, in which it promotes cell differentiation, endoplasmic reticulum stress, and apoptotic death [443], while another study proposed a role of dietary vitamin D in the growth and maturation of mouse intestinal *Lgr5<sup>+</sup>* cells [444]. Curiously, in a mouse model of IBD, locally high  $1,25(\text{OH})_2\text{D}$  concentrations produced by engineered inflammation- and gut-homing macrophages enhanced the migration of intestinal stem cells that later differentiated into mature epithelial cells [445]. It is worth noting that little coincidence exists between target genes of  $1,25(\text{OH})_2\text{D}_3$  in human and mice colon organoids [434], which agrees with global minimal intersection between genes regulated by  $1,25(\text{OH})_2\text{D}_3$  or analogs in the two species found in 94 gene profiling studies [446].

## 5. Animal models

Numerous studies using experimental animals support the protective action of vitamin D,  $1,25(\text{OH})_2\text{D}_3$ , and several  $1,25(\text{OH})_2\text{D}_3$  analogs against CRC.

### 5.1 Diet studies and chemically induced colorectal cancer models

Prolonged feeding (104 weeks) of mice with a “Western-style diet” (WD), containing reduced calcium and vitamin D<sub>3</sub> and the fat level of the average human Western diet, generates single-crypt dysplastic lesions and focal hyperplasia in the colon [447]. In short-term studies (up to 20 weeks) feeding normal rodents with WD induces epithelial cell hyperproliferation in the exocrine pancreas and prostate, and cell hyperplasia and hyperproliferation in the colon and mammary gland. Conversely, WD containing more calcium and vitamin D<sub>3</sub> prevents the hyperproliferation of epithelial cells in those organs [448]. Similar results were obtained with a new Western diet (NWD) that contains additional nutritional risk factors (lower levels of donors to the single carbon pool and lower fiber) and reflects the intake levels of nutrients that are major dietary risk factors for human CRC. The NWD induces colonic tumors when fed to wild-type C57BL/6J mice for two-thirds of their lifespan. Elevating dietary calcium and vitamin D to the upper levels consumed by humans prevents

tumor development. Importantly, tumorigenesis is not altered by a similar increase in folate, choline, methionine, or fiber, each of which is also at low levels in the NWD and is associated with elevated CRC risk [449]. Moreover, C57BL/6J mice fed with the NWD from weaning display higher inflammatory responses than controls, including macrophage-associated crown-like structures in epididymal adipose tissue and elevated serum concentrations of the proinflammatory cytokine IL-1 $\beta$  and its targets, Mcp-1 and Rantes, which were prevented or importantly diminished in the NWD group supplemented with high vitamin D<sub>3</sub> and calcium. Thus, elevating vitamin D and calcium in the NWD can reduce the inflammation associated with increased risk of colon tumor development [450].

The effect of dietary vitamin D on Wnt/ $\beta$ -catenin signaling has been investigated in the healthy colon of mice fed with a modified AIN-93G diet containing either 100 IU vitamin D<sub>3</sub>/kg diet (low vitamin D) or 2500 IU vitamin D/kg diet (high vitamin D). In mice fed with a high vitamin D diet, the levels of Wnt5A and Ror2, which promote degradation of  $\beta$ -catenin, were upregulated, whereas  $\beta$ -catenin and Tcf4 protein expression was reduced. This suggests that vitamin D decreases  $\beta$ -catenin levels in the normal colon partially through this mechanism [220]. Additionally, in the healthy colon of mice, high vitamin D augments the expression of CaSR and differentiation and apoptosis markers, while it reduces that of diverse proliferation markers [341].

Numerous studies have reported that 1,25(OH)<sub>2</sub>D<sub>3</sub> reduces the number of tumors generated by chemical carcinogens in mice or rats (reviewed in Ref. [451]). In a study, female C57BL/6J mice were fed with increasing vitamin D<sub>3</sub> concentrations and treated with AOM followed by the tumor promoter DSS to induce preneoplastic dysplastic lesions. Interestingly, dietary vitamin D<sub>3</sub> concentration correlates inversely with dysplasia score and positively with serum 25(OH)D levels. Therefore, high-dietary vitamin D<sub>3</sub> intake can prevent chemically induced preneoplastic lesions. The maximum impact is achieved in mice that consume more than 2500 IU vitamin D/kg diet [452]. In another study, A/J mice that received the Ro26-2198 analog or vehicle by miniosmotic pump were treated with AOM and DSS, which induces colitis and promotes AOM-induced tumors. Remarkably, Ro26-2198 delays the onset of clinical colitis and blocks the development of the colonic dysplastic foci induced by AOM/DSS treatment. Compared with control animals, AOM/DSS significantly increases Myc, Cox-2, and p-Erk, while Ro26-2198 abolishes these increases [372].

A study examined the potential synergistic chemopreventive effects of vitamin D and metformin against the development of early colon neoplasia in two animal models: 1,2-dimethylhydrazine dihydrochloride

(DMH)-induced CRC rat model and DMH-DSS-induced colitis-associated colon neoplasia mouse model. Combined use of vitamin D and metformin shows a more pronounced effect on reducing the number of colonic aberrant crypt foci and tumors compared with either vitamin D or metformin alone. Likewise, the enhancement of metformin chemopreventive effects by vitamin D is associated with the downregulation of ribosomal S6 protein expression, via the AMPK (IGF-I)/mTOR pathway, while that of vitamin D action by metformin is related to inhibition of the expression of Myc and cyclin D1 proteins via the antagonism of the Wnt/ $\beta$ -catenin pathway [322]. In addition, in AOM-treated Wistar rats, vitamin D and 5-FU synergize and exhibit stronger anticancer effects in combination than in single treatments by modulating the Wnt/ $\beta$ -catenin pathway, TGF- $\beta$ 1 signals, iNOS, Cox-2, and Hsp90 [373].

Benninghoff and colleagues have reported that AOM combined with DSS or *Apc*<sup>Min/+</sup> mouse models of colitis-associated colorectal carcinogenesis (CAC) fed with TWD (a new total WD that emulates a typical WD using available US nutrient intake survey data, which has less calcium and vitamin D than AIN93G diet) developed more severe and more prolonged colitis compared with those fed with AIN93G diet, leading to markedly enhanced colon tumorigenesis. Restoration of calcium and vitamin D inverted the proinflammatory effects of the vitamin D-deficient TWD diet on mucosal gene expression, suggesting a reduction of the symptoms of colitis following DSS treatment, and improved the tumor-promoting effects of TWD [453]. Elimrani and colleagues studied the effect of vitamin D in a mouse model that presented a deficiency in the expression of *Nod2*, a gene that is induced by vitamin D and whose deficiency impairs intestinal epithelial integrity and enhances inflammation. Upon treatment of C57BL/6J and *Nod2*<sup>-/-</sup> mice with AOM and DSS, those with vitamin D deficiency developed more severe colitis than those supplemented with vitamin D, with higher colitis activity index, greater weight loss, increased histological inflammation score, and IL-6 in the mucosa. Overall incidence of colonic tumors was not significantly different between both groups, but vitamin D-deficient mice had higher tumor multiplicity and lower survival rate [454]. After treatment with AOM and DSS, vitamin D-deficient and vitamin D-supplemented mice showed reduced plasma levels of 25(OH)D<sub>3</sub> and reduced expression of *Cyp24a1* and *Vdr* genes (both mice strains) compared with saline-treated controls on the vitamin D-deficient diet. Thus, vitamin D supplementation in both C57BL/6J and *Nod2*<sup>-/-</sup> mice reduced colitis severity and decreased the number of inflammation-associated CRC tumors independently of *Nod2* [454].

## 5.2 Xenografted mice

Human tumor cells implanted subcutaneously into immunosuppressed mice (xenografts) are commonly used as an *in vivo* approach in preclinical anticancer drug development studies. In 1987, Eisman and colleagues reported the suppression by  $1,25(\text{OH})_2\text{D}_3$  of the growth of xenografts generated by VDR-positive human cancer cell lines (COLO206F and COLO239F, established from a CRC and a malignant melanoma, respectively) [455]. Since then, several studies using  $1,25(\text{OH})_2\text{D}_3$  or its analogs have supported these results. In mice implanted with HT29 cells, administration of 0.1- and 0.2- $\mu\text{g}$   $1,25(\text{OH})_2\text{D}_3$  three times/week does not cause significant xenograft growth delay, whereas the synthetic analog Ro25-6760 ( $1,25(\text{OH})_2$ -16-ene-23yne-26,27-hexafluoro-19-nor- $\text{D}_3$  that has increased agonist activity due in part to protection from degradation), at both doses, causes significant tumor growth inhibition in comparison with vehicle-treated mice. Remarkably, in 30% of the mice treated with Ro25-6760, the tumors disappear during treatment and tumor growth does not resume after drug withdrawal. Neither  $1,25(\text{OH})_2\text{D}_3$  nor Ro25-6760 displays a growth-inhibitory effect at any concentration on xenografts generated by VDR-negative SW620 CRC cells [456]. In addition, HT29 xenografts generated in paricalcitol (19-nor- $1,25(\text{OH})_2\text{D}_2$ )-treated mice are smaller and weigh less than those developed in vehicle-treated mice [457]. Accordingly, the calcipotriene-based  $1,25(\text{OH})_2\text{D}_3$  analogs BGP-13 and BGP-15 inhibit the growth of HT29 tumor xenografts [318]. Huang and colleagues have reported that calcitriol suppresses Warburg effect in HT29 cells. It reduces the volume and weight of HT29 xenografted tumors as compared with the control group, and the expression levels of GLUT1 and glycolytic enzymes hexokinase 2 and lactate dehydrogenase A are also lower in the calcitriol group [458]. Moreover, Balb/c mice fed with a vitamin  $\text{D}_3$ -deficient diet (vitamin  $\text{D}_3$ -deficient mice), or a diet supplemented with vitamin  $\text{D}_3$  (vitamin  $\text{D}_3$ -sufficient mice) were injected with MC26 CRC cells. Interestingly, the tumors developed in vitamin  $\text{D}_3$ -sufficient mice are 40% smaller than those generated in vitamin  $\text{D}_3$ -deficient mice. In addition, the RNA expression of *VDR* and *CYP27B1* was higher in vitamin  $\text{D}_3$ -sufficient than in vitamin  $\text{D}_3$ -deficient mice [459].

A study using mice injected with HT29 cells stably overexpressing CYP24A1 or Mock cells and fed with either a high (2500 IU/kg) or a low (100 IU/kg) vitamin  $\text{D}_3$  diet in the presence or absence of soy (20% diet content) showed that, regardless of dietary vitamin  $\text{D}_3$  levels, xenografts overexpressing CYP24A1 grow faster and are heavier and more aggressive than those

generated by Mock cells. Irrespective of vitamin  $\text{D}_3$ , dietary soy increases tumor volume in xenografts that overexpress CYP24A1 [138], which suggests that the combination of vitamin  $\text{D}_3$  and soy could have an antitumorigenic effect only if CYP24A1 levels are normal, or that genistein in soy can inhibit the endogenous and normally regulated CYP24A1 but cannot downregulate forced overexpression of the gene [460].

Padi and colleagues have suggested a role of *miR-627* mediating the suppressive actions of vitamin D on tumor xenografts in mice. Thus, calcitriol induces the expression of *miR-627*, which downregulates Jumonji domain containing 1A (JMJD1A) histone demethylase and suppresses growth of HCT116 cells xenografted tumors in nude mice. Overexpression of *miR-627* prevents growth of these tumors in mice, while blocking the activity of this *miR* inhibits the suppressive effects of vitamin D [461].

*In vivo* models have also been used to investigate the biological effect of combined therapies against CRC. In mice bearing MC38 xenografts, two  $1,25(\text{OH})_2\text{D}_3$  analogs (PRI-2191-tacalcitol and PRI-2205-5,6-trans-isomer of calcipotriol) significantly enhance the antitumor activity of 5-FU, although the results depend on the treatment regimen. In comparison with administration of 5-FU alone, the optimal schedule of combined therapy shows a significant decrease in tumor growth and metastasis and prolongs mouse survival. Both combinations display a synergistic effect and do not cause toxicity. In addition, both analogs prolong the antitumor effect of 5-FU after the completion of drug administration. Potentiation of the activity of capecitabine, a pro-drug of 5-FU, by the  $1,25(\text{OH})_2\text{D}_3$  analogs was, also observed [462]. Furthermore, both combined therapies inhibit the growth of xenografted HT29 cells by a mechanism involving an increase in  $\text{p21}^{\text{CIP}}$  and a decrease in phosphorylated ERK1/2 levels, which may lead to a reduction in thymidylate synthase expression [463]. Moreover, the combined treatment of  $1,25(\text{OH})_2\text{D}_3$  analogs with irinotecan or oxaliplatin significantly inhibits MC38 tumor growth and prolongs mouse survival. Treatment with  $1,25(\text{OH})_2\text{D}_3$  analogs and oxaliplatin also improves the antitumor effects of these compounds in mice bearing HT29 tumors, but an antagonist effect on lifespan prolongation was found [464].

Kim and colleagues have reported that the vitamin D analog calcipotriol can be used as an adjunct to sensitize or prime colorectal cancer cells to oncolytic viro-immunotherapy. Thus, calcipotriol has an additive effect to poxvirus CF33-based viral therapy in an HT29 xenograft model of CRC but not in HCT116 xenografted tumors. RNA-seq and gene expression data analyses demonstrated a downregulation of the JAK/STAT signaling pathway in those HT29 tumors treated with

calcipotriol suggesting that the antiinflammatory properties of vitamin D may enhance the effects of viral therapy in some tumors [465]. Likewise, 1,25(OH)<sub>2</sub>D<sub>3</sub> is also able to sensitize CRC xenograft models to radiotherapy, and proteomic analyses have shown that the mechanism underlying this sensitivity also involves a partial block of the JAK/STAT signaling pathway [466].

### 5.3 Genetic models of colorectal cancer and *Vdr*-deficient mice

#### 5.3.1 Genetic models of CRC

The multiple intestinal neoplasia (Min; *Apc*<sup>Min/+</sup>) model was established from an ethylnitrosourea-treated C57BL/6J male mouse [467] and carries a nonsense mutation at codon 850 of the tumor suppressor *Apc* gene, which causes a truncated *Apc* polypeptide [468] and the consequent accumulation of nuclear β-catenin in the affected cells. This alteration leads to the development of numerous adenomas throughout the intestinal tract of young adult *Apc*<sup>Min/+</sup> mice. The *Apc*<sup>Min/+</sup> animal model is the most widely used for human CRC because of the phenotypic and genetic similarities between murine *Apc*<sup>Min/+</sup> and human FAP, and mutation of the *APC* gene occurs somatically during the development of most sporadic human colorectal tumors. However, the model is not optimal, because mice develop mostly small intestine tumors [468].

Tumor number in female *Apc*<sup>Min/+</sup> mice at 4–5 weeks of age is not affected by 10 weeks of treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> or its analog 1,25(OH)<sub>2</sub>16-ene-19-nor-24-oxo-D<sub>3</sub> (Ro 26-9114). However, a significant decrease in total tumor load (the sum of all polyp areas) over the entire gastrointestinal tract is observed in the analog and the 1,25(OH)<sub>2</sub>D<sub>3</sub> groups [469]. Accordingly, treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub>, QW (QW-1624F2-2-1-α-hydroxymethyl-16-ene-24,24-difluoro-25-hydroxy-26, 27-bishomo-D<sub>3</sub>), or BTW (2,2-dimethylated-19-nor analogue) enhances osteopontin expression, but inhibits that of CD44, the osteopontin receptor implicated in cell growth. These treatments also enhance E-cadherin expression and promote the inhibition of β-catenin nuclear localization and of Tcf1 and Myc protein expression in the *Apc*<sup>Min/+</sup> intestine [470].

Rebel and colleagues demonstrated for the first time an inhibitory effect of moderate UV exposure on the outgrowth and malignant progression of intestinal tumors developed in *Fabp1Cre;Apc*<sup>15lox/+</sup> mice, which at least in part is mediated by vitamin D<sub>3</sub> as UV irradiation increased 25(OH)D<sub>3</sub> serum levels in male and female mice. The tumor load at 7.5 months of age was significantly reduced in both the vitamin D<sub>3</sub>-supplemented and the UV-exposed (daily UV irradiated from 6 weeks of age) groups compared with control animals, but no

reduction in tumor number was found [471]. The effects of a WD were also tested in mice carrying targeted mutations that lead to intestinal and colonic neoplasia. Yang and colleagues generated mice with an insertion of a neomycin phosphotransferase expression cassette at codon 1638 in exon 15 of the *Apc* gene. *Apc*<sup>1638/+</sup> mice develop colonic polyps early in life, and adenomas and carcinomas primarily in the small intestine later in their lifespan. Interestingly, a WD increases the incidence of carcinomas and invasive tumors developed by these mice, which suggests that vitamin D deficiency increases tumor aggressiveness [472].

To avoid issues of species specificity in animal modeling of human disease, Irving and colleagues used two genetic models of familial CRC: the *Apc*<sup>Pirc/+</sup> (*Pirc*) rat and the *Apc*<sup>Min/+</sup> mouse. Treatment with 25(OH)D<sub>3</sub> or two 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs (HP or NC) for 11–16 weeks neither reduced tumor multiplicity nor caused tumor regression of colonic tumors in these models. The authors proposed that the lack of response might be due to reduced tumor *Vdr* expression or to insufficient treatment duration, and it is also possible that the analogs had no effect on animals that were already vitamin D sufficient or that the endoscopic procedure used underestimated the number of tumors [473]. In addition, Irving and colleagues tested whether vitamin D deficiency plays a causative role in tumor development using two strains of the *Apc*<sup>Pirc/+</sup> rat, which contain a truncating mutation in the *Apc* gene and differ in their susceptibility to intestinal tumorigenesis. In the colon, vitamin D deficiency did not increase the development of tumors in either strain and was actually protective in one strain. Unexpectedly, low-dietary calcium combined with vitamin D deficiency significantly suppressed tumor development in the small intestine and colon of both strains [474]. A study using *Apc*<sup>Δ14/+</sup> mice that harbor a frameshift mutation within exon 14 showed that vitamin D<sub>3</sub> does not reduce tumor formation. There was no difference in the number or size of the tumors developed in the small intestine. However, in the colon, there was a trend toward reduction in tumor frequency and load, but this effect did not reach statistical significance. The authors found extensive loss of *Vdr* expression in these tumors, which could explain the lack of CRC protection afforded by vitamin D<sub>3</sub> in this model [475]. Similarly, a study on hyperplastic colonic lesions of *CAC;Apc*<sup>Δ580/Δ580</sup> mice (transgenic mice with colon-specific deletion of both *Apc* alleles) has shown that short-term exposure to pharmacological doses of 1,25(OH)<sub>2</sub>D<sub>3</sub> does not suppress colonic Wnt/β-catenin signaling. Although 1,25(OH)<sub>2</sub>D<sub>3</sub> activates classical *Vdr* target genes (e.g., *Cyp24a1* and *Trpv6*) in the colon of *CAC;Apc*<sup>Δ580/Δ580</sup> and control mice, it does not reduce the elevated RNA levels of β-catenin target genes or the high proliferation index observed in *CAC;Apc*<sup>Δ580/Δ580</sup>

mice. Again, these results could be explained by the lower levels of *Vdr* RNA and protein in the colon of *CAC;Apc<sup>4580/4580</sup>* mice than in that of control animals, which indicates a loss of colon responsiveness to vitamin D compounds. It also seems that the use of 1,25(OH)<sub>2</sub>D<sub>3</sub> or analogs to suppress  $\beta$ -catenin signaling is limited and that tumors with complete loss of *Apc* function may be resistant to vitamin D action [476].

In another study, upon AOM + DSS treatment, the levels of *Il-6* and *Tnf- $\alpha$*  RNA were higher in untreated mice than in those supplemented with vitamin D. Accordingly, while the untreated group showed an inflammatory cell infiltration and interstitial connective tissue hyperplasia, mice treated with 1500 IU or 3000 IU of vitamin D had a relatively clear structure of colon layers with only mild edema and less inflammation. Vitamin D induced mucin (*Muc*)2 expression, which can be considered as a beneficial response that could enhance the protective action of the mucus barrier, but inhibited *Muc1* gene expression, the major membrane-bound mucin in the colon that plays a role in cell signaling and damage repair [477]. In this study, vitamin D diet modulated the expression level of key genes in microbial defense and injury-repair responses. Thus, it upregulated resistin-like molecule  $\beta$ , a goblet cell secretory hormone that enhances colon barrier function and regulates colitis, and there was a trend toward downregulation of regenerating islet-derived protein 3  $\gamma$ , which is an antibacterial C-type lectin [477].

Interestingly, *Smad3*<sup>-/-</sup> mice (which have defective Tgf- $\beta$ -signaling and develop colitis and colitis-associated CRC after the administration of DSS) treated with DSS and fed with a vitamin D-null diet showed improved survival, reduced incidence and severity of colonic dysplasia, and decreased colon tumor incidence compared with mice fed a control diet. These effects correlated with increased epithelial cell proliferation and repair at early stages of the disease. As suggested by the authors, vitamin D deficiency may be beneficial in some cases of CAC, possibly by promoting intestinal healing [478].

### 5.3.2 *Vdr*-deficient mice

Four groups have independently generated *Vdr*-deficient mice (*Vdr*<sup>-/-</sup>) by disrupting of the *Vdr* DNA-binding domain using different targeting constructs and mouse strains. Abnormalities in all *Vdr*<sup>-/-</sup> mice develop only after weaning, showing a phenotype with the appearance of hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, alopecia, and severely impaired bone formation, leading to growth retardation, severe rickets, and osteomalacia; the typical features of vitamin D-dependent rickets type II [479–482]. The expression of 8-hydroxy-20-deoxyguanosine (8-OHdG), a marker of oxidative

DNA damage, is significantly augmented in the colon of *Vdr*<sup>-/-</sup> mice. In addition, an increased level of the proliferation marker PCNA is observed in *Vdr*<sup>-/-</sup> mice colon progeny. The presence of only a partially functional 1,25(OH)<sub>2</sub>D<sub>3</sub>/*Vdr* system in the colon of *Vdr*<sup>+/-</sup> animals can reduce by 40% the expression of 8-OHdG compared with *Vdr*<sup>-/-</sup> animals. Thus, the partial or complete lack of 1,25(OH)<sub>2</sub>D<sub>3</sub>/*Vdr* action results in colonic premalignant alterations [122].

Two independent groups generated *Apc*<sup>Min/+</sup>*Vdr*<sup>-/-</sup> mice by breeding. No differences were reported in the number of small intestinal and colonic tumors between *Apc*<sup>Min/+</sup>*Vdr*<sup>+/-</sup> and *Apc*<sup>Min/+</sup>*Vdr*<sup>-/-</sup>. However, size of the tumors was significantly higher in *Apc*<sup>Min/+</sup>*Vdr*<sup>-/-</sup> mice [247,483]. These observations suggest that the increased tumor burden in *Apc*<sup>Min/+</sup>*Vdr*<sup>-/-</sup> mice is probably due to loss of the inhibitory effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on tumor growth rather than on tumor initiation in the intestine [483]. Moreover, both aberrant crypt foci and carcinomas in *Apc*<sup>Min/+</sup>*Vdr*<sup>-/-</sup> mice showed higher expression of nuclear  $\beta$ -catenin and  $\beta$ -catenin/TCF target genes than those developed in *Apc*<sup>Min/+</sup>*Vdr*<sup>+/-</sup> mice. Consistently, *Vdr* depletion in cultured CRC cells increases  $\beta$ -catenin nuclear levels and transcriptional activity and abrogates the capacity of 1,25(OH)<sub>2</sub>D<sub>3</sub> to promote the relocation of  $\beta$ -catenin from the nucleus to the plasma membrane and to inhibit  $\beta$ -catenin/TCF target genes [247]. Moreover, total *Vdr* knockout (*Vdr*<sup>-/-</sup>) and intestinal epithelial *Vdr* knockout (*Vdr*<sup>ΔE1C</sup>) mouse models led to lower expression of claudin-5 in colon tissue, while overexpression of *Vdr* in intestinal epithelial cells led to an increase of claudin-5 and a decrease of the inflammatory cytokines *Il-1 $\beta$*  and *Il-17* compared with control mice [484].

The summary from studies using animal models and diverse experimental approaches appears to be that vitamin D compounds protect against intestinal carcinogenesis provided that VDR is expressed in CRC cells and that lack of VDR per se does not cause CRC, but it increases CRC susceptibility/risk in response to insults, mutations, or an unhealthy diet.

## 6. Conclusion

The data presented show that 1,25(OH)<sub>2</sub>D<sub>3</sub> exerts a wide array of effects on several types of cells that collectively support a protective action against CRC (Fig. 89.3). 1,25(OH)<sub>2</sub>D<sub>3</sub> affects not only colorectal carcinoma cells but also nontumoral CAFs and possibly other stromal cell types, as well as colorectal organoids composed of normal or cancer stem cells and their progeny. Accordingly, vitamin D compounds inhibit the tumorigenic process in a variety of in vivo animal models of CRC. Given the key importance of the Wnt/

$\beta$ -catenin signaling pathway in CRC, its multilevel antagonism in carcinoma cells appears as an important mechanism of  $1,25(\text{OH})_2\text{D}_3$  action. Therefore, the results of preclinical studies agree with a large number of epidemiological studies showing CRC as the neoplasia most strongly associated with vitamin D deficiency and are highly indicative of causality. However, this contrasts with the unclear results of intervention/supplementation studies, which may be due to deficiencies in their design and analysis, and to our insufficient knowledge of the optimal vitamin D compounds dosage and administration. The extreme health impact of CRC warrants the continuation of the study of vitamin D action.

## 7. Summary points

- $1,25(\text{OH})_2\text{D}_3$  inhibits the proliferation and invasiveness and promotes the differentiation of colon carcinoma cells.
- $1,25(\text{OH})_2\text{D}_3$  antagonizes the Wnt/ $\beta$ -catenin pathway in colon carcinoma cells by a variety of mechanisms.
- $1,25(\text{OH})_2\text{D}_3$  reduces cell proliferation and protumoral phenotype in cultures of CRC patient-derived stromal tumor fibroblasts and in 3D colon organoids.
- $1,25(\text{OH})_2\text{D}_3$  attenuates tumor growth in several animal models of CRC.

## OBJECTIVES

- Lung cancer has always been viewed and studied as a heterogenous disease. This chapter seeks to explore the role of vitamin D in lung cancer risk and survival in the context of disease heterogeneity.
- Our goal is to promote a thoughtful precision guided future evaluation of vitamin D in lung cancer. This chapter offers an insight into the current knowledge of subtype-specific antitumor activity of vitamin D to facilitate such an evaluation.

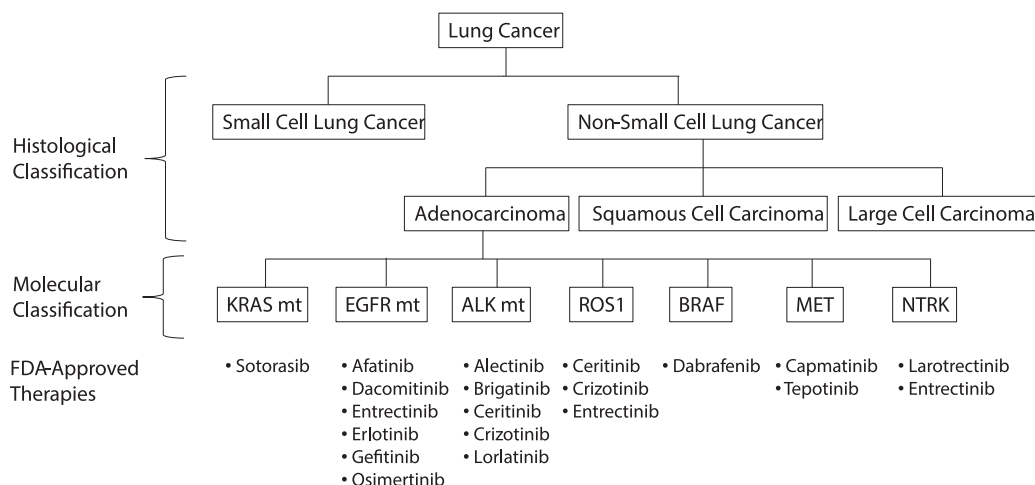

chemoprevention in individuals at high risk for disease, improved adjuvant therapies for early-stage disease, and personalized therapies for advanced disease. Is there a role for vitamin D in this context? A PubMed search of “vitamin D and lung cancer” resulted in a list of nearly 500 publications. Published results do not support a ubiquitous role for vitamin D in preventing progression of lung cancer. Rather, benefit of vitamin D supplementation may be restricted to specific patient subsets. This chapter will consider which patients have potential to respond to vitamin D and why such patient-specific differences exist. Ultimately, well-informed clinical trials of precision vitamin D supplementation will be needed to test hypotheses and establish efficacy in the management of lung cancer.

Central to the theme of this chapter is recognition that lung cancer is not a single disease. Rather, it is a collection of diseases that are distinguished based on their histology and molecular profiles (Fig. 90.1). Historically, lung cancer is categorized based on histology (small-cell lung cancer [SCLC] versus non-small cell lung cancer [NSCLC]). SCLC encompasses 10%–15% of all lung cancers. Almost all patients diagnosed with SCLC have a history of smoking. As the name suggests, these tumors are comprised of cancer cells that are small and round in appearance. SCLCs grow and spread faster than NSCLCs, and patients diagnosed with SCLC have a dismal 5-year survival rate of only 6% [5]. One-third of patients will be diagnosed with limited stage SCLC,

## 1. Introduction

Lung cancer is the second most frequently diagnosed cancer in men and women, with >236,000 cases expected to be diagnosed in 2022 [1]. Lung cancer remains the leading cause of cancer-related deaths in both sexes, despite advances in diagnostics, surgery, and therapy. Tobacco smoking is a primary cause of disease, accounting for nearly 85% of all lung cancers [2]. Strategies to reduce lung cancer mortality are multifold and include enhanced lung cancer screening, tobacco cessation,

**FIGURE 90.1 Classification and treatment of lung cancer.** Lung cancer is subclassified based on histology and molecularly, based on the presence of oncogenic driver mutations. Oncogenic drivers in LSCC (reviewed in Ref. [3]) are distinct from the validated oncogenic drivers found in LUAD. To date, molecularly targeted therapies have had a greater impact in LUAD compared with LSCC. In the United States, an oncogenic driver is identified in 64% of LUAD [4]. *EGFR* mutations (mt) and *ALK* translocations are enriched among females, younger patients, and lifetime never smokers. *KRAS* mt are more frequently observed in patients with a significant history of tobacco smoke exposure. FDA-approved drugs that target specific oncogenic drivers in LUAD are shown.

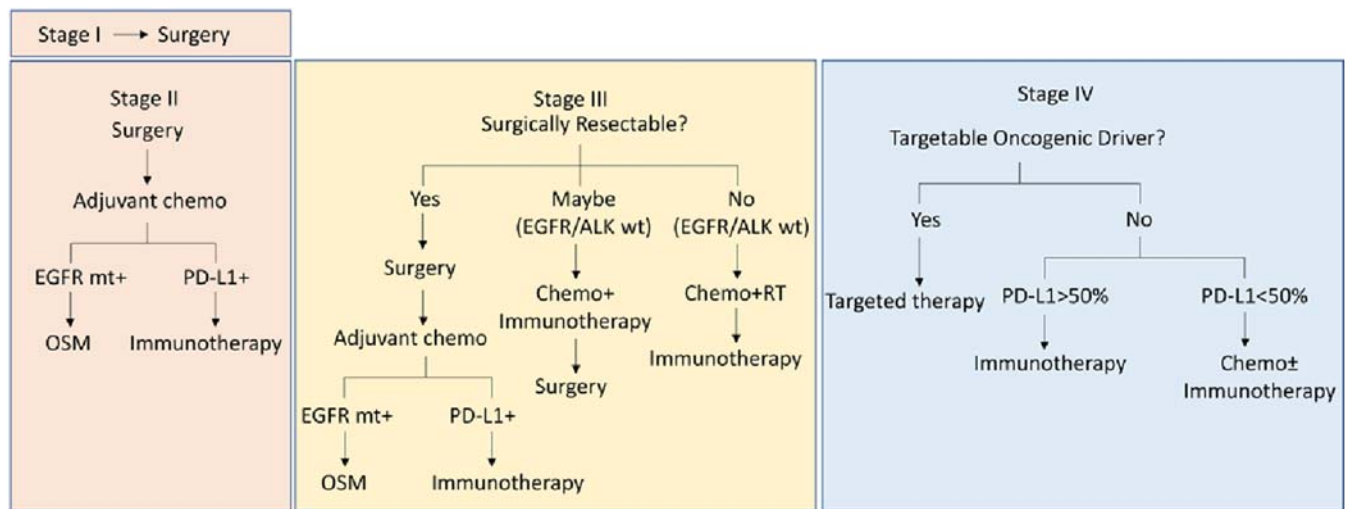

where more opportunity for therapeutic intervention exists [6]. Treatment options for limited stage SCLC include surgery, chemotherapy, radiation, a combination of chemotherapy and radiation (chemoradiation), and immunotherapy [7]. Most cases are treated in a multi-therapy approach, according to the National Comprehensive Cancer Network (NCCN) guidelines. Treatment of limited-stage SCLC produces 5-year survival rates of up to 27%. Two-thirds of SCLC patients will present with extensive disease and have poor prognosis. Patients with extensive SCLC receive systemic therapy that typically includes multiple cycles of chemotherapy with a platinum-based doublet. Chemotherapy may be combined with contemporary immunotherapy or radiation therapy. Radiation therapy becomes a more common treatment method when SCLC has spread to the brain. Overall survival for extensive stage SCLC is approximately 10 months, with most patients developing recurrent disease after initial treatment [7]. Very few studies have investigated the role of vitamin D specifically in SCLC. Therefore, this disease will not be considered further in the chapter.

NSCLC accounts for 80%–85% of all lung cancers. There are three major subtypes of NSCLC, which differ in their cell of origin, anatomic location, and treatment options (Fig. 90.1). Adenocarcinoma of the lung (LUAD) represents around 40% of all NSCLC cases and arises from secretory cells in the distal airways. Squamous cell carcinoma of the lung (LSCC) accounts for 30% of NSCLC cases and arises from bronchial epithelial cells that line the central airways. LSCC is more tightly associated with smoking than LUAD. Large

cell carcinoma is the least common of the three major subtypes, accounting for 5%–10% of all cases, and can appear in any part of the lung. These cancers grow and spread quickly and can have similar features to those of SCLC histology.

Treatment options for NSCLC are dictated by numerous factors including histologic subtype, staging, and in the case of LUAD, by tumor mutation profiles and expression of the immune checkpoint, PD-L1 (Fig. 90.2, [8]). The TNM system is used for NSCLC staging. T denotes tumor size. N relates to the number of lymph nodes to which the cancer has spread. M stands for metastasis and indicates that cancer has spread across or out from the lung to another part of the body. A lower TNM score (stage I) carries a better prognosis than a higher score (stage IV). Patients diagnosed with early-stage NSCLC receive surgery with curative intent. Surgery may also be used in patients with stage III disease, but presurgical (neoadjuvant) or postsurgical therapies are also required. Patients diagnosed with stage IV cancers receive systemic therapy. Remarkable gains in survival of patients with advanced NSCLC have been achieved over the past decade due to the incorporation of targeted therapies and immunotherapies (immune checkpoint inhibitors) into treatment regimens. Success of these therapies in advanced disease has led to their subsequent evaluation and approval by the FDA for use at earlier stages. For example, osimertinib (OSM) received approval for use in advanced disease in 2015 and as adjuvant therapy in early-stage disease in late 2020.

Targeted therapy relies on the identification of molecular drivers of the cancer. Oncogenic drivers encode

**FIGURE 90.2** Lung cancer treatment varies by stage at diagnosis and molecular features of tumor. Algorithms that are used to identify stage-specific and genotype-specific treatments for NSCLC are shown. Illustration is meant to be representative and is not inclusive for all possible therapies that may be used. Surgery is performed with curative intent for stage I and stage II disease. Targeted therapies and immunotherapies, which have revolutionized the treatment of advanced disease, are now safely and effectively deployed at earlier disease stages.

proteins whose activity is required for tumor cell survival: Inhibition of the abnormal protein results in tumor growth suppression [9–11]. Multiple FDA-approved drugs have been developed that selectively and effectively inhibit several of the oncogenic drivers of LUAD including the epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase (ALK), and BRAF (v-Raf murine sarcoma viral oncogene homolog B) (Fig. 90.1). In May 2021, the first drug to selectively inhibit KRAS G12C (sotorasib) was FDA-approved [12]. A 1-year benefit in overall survival is obtained in patients diagnosed with advanced LUAD who receive therapy that is matched to the oncogenic driver expressed in their lung tumor (so-called, personalized medicine) versus those who do not receive genotype-matched therapy [4]. As a result, it is standard practice to sequence lung tumors from advanced NSCLC patients prior to therapy selection. Although these targeted therapies provide survival benefit of 1–2 years in some cases, drug resistance will inevitably develop [13–15]. This highlights the need to develop innovative approaches to extend the durability and efficacy of targeted therapies.

Immunotherapy involves the administration of antibodies (referred to as immune checkpoint inhibitors) that block the interaction between an immune checkpoint protein expressed on CD8+ T cells (for example, PD-1) and its cognate partner expressed on lung tumor cells (PD-L1). The binding of PD-L1 to PD-1 inhibits T cell killing of the tumor cell. By disrupting this inhibitory interaction, immune checkpoint inhibitors promote T cell-mediated antitumor activity. Immune checkpoint inhibitors that are approved for use in NSCLC include

nivolumab (anti-PD-1), pembrolizumab (anti-PD-1), atezolizumab (anti-PD-L1), durvalumab (anti-PD-L1), and ipilimumab (anti-CTLA4). The objective response rate to immune checkpoint inhibitors is approximately 30%. Biomarkers that distinguish responders versus nonresponders have been developed to avoid use of an ineffective therapy that can have serious immune-related toxicities. Expression of the biomarker PD-L1, tumor mutation burden, and microsatellite instability are now routinely used to identify patients who are more likely to derive benefit from immunotherapy [16].

## 2. Vitamin D may have tumor cell intrinsic and tumor cell extrinsic activities in lung cancer

The presence of vitamin D receptor (VDR) in cells/target tissues is required for generating a response to vitamin D metabolites. The VDR is expressed in premalignant lesions and some lung tumors [17], raising the possibility that tumor-intrinsic vitamin D signaling occurs and may be exploited in the chemoprevention or treatment of lung cancer. However, VDR is also expressed in a variety of immune cells, including T cells, where it regulates differentiation and effector function [18–20]. Vitamin D signaling within immune cells may be critically important in modulating the efficacy and toxicity of immune checkpoint inhibitors. The existence of VDR in multiple cell types within the tumor microenvironment and the differential importance of vitamin D signaling events in different disease and treatment contexts prevents a one-size-fits all response to the question of whether vitamin D plays a role in lung

cancer. To address this complexity, we summarize current knowledge regarding the role of vitamin D across the lung cancer treatment continuum based on disease stage and treatment type.

### 3. The role of vitamin D in the chemoprevention of non–small-cell lung cancer

The chemopreventive effects of vitamin D metabolites have been tested using both murine models of LUAD [21] and LSCC [22]. LUAD is induced in A/J mice using the tobacco carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK) [23]. The ability of 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>) to modify lung tumorigenesis in the NNK model was investigated by Mernitz et al. [21]. Mice received control, AIN-93M diets, or the same AIN-93M diet supplemented with 1,25(OH)<sub>2</sub>D<sub>3</sub> (2.5 or 5.0 µg/kg diet) for 3 weeks before and 17 weeks after NNK administration. 1,25(OH)<sub>2</sub>D<sub>3</sub> supplementation resulted in statistically significant and dose-dependent decreases in both lung tumor incidence (reduced 82% at 5.0 µg/kg 1,25(OH)<sub>2</sub>D<sub>3</sub>) and multiplicity (reduced 98% at 5.0 µg/kg 1,25(OH)<sub>2</sub>D<sub>3</sub>). However, 1,25(OH)<sub>2</sub>D<sub>3</sub> supplementation at this dose was not well tolerated: Mice experienced significant weight loss and dose-dependent kidney calcification, consistent with toxicity due to hypercalcemia.

LSCC develops from the normal bronchial epithelium through a progressive series of molecular and histologic changes (reviewed in Ref. [24]). Histologic progression includes basal cell hyperplasia, squamous metaplasia, dysplasia, carcinoma in situ, and invasive LSCC. The VDR is expressed within histologically normal bronchial epithelium, metaplastic lesions, and dysplastic lesions [17]. It is therefore plausible that VDR signaling can be activated within premalignant lesions by dietary vitamin D<sub>3</sub> or 1,25(OH)<sub>2</sub>D<sub>3</sub> to delay development of LSCC. To study the chemopreventive effects of vitamin D in this disease context, Mazzilli et al. [22] employed the N-nitroso-tris-chloroethylurea (NTCU) model. NTCU is a chemical carcinogen that induces premalignant bronchial lesions that progress to frank lung SCC in mice [25]. SWR/J mice were maintained on a deficient diet containing no vitamin D<sub>3</sub> or a sufficient diet containing 2000 IU/kg vitamin D<sub>3</sub>. Mice on either diet received NTCU on a chronic basis. At study termination, the percentage of the mucosal surface of large airways occupied by high-grade dysplastic lesions was 22.7% in vitamin D–deficient mice and 8.7% in vitamin D–replete mice. Proliferation and inflammation were both significantly increased in NTCU-treated, vitamin D–deficient mice compared to NTCU-treated, vitamin D–replete mice. These studies support the conclusion that vitamin D repletion reduces the progression of

premalignant lesions and so may suppress development of lung SCC. Interestingly, Mazzilli et al. also evaluated the effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> supplementation (80 µg/kg weekly, ip) on disease progression in the NTCU model. 1,25(OH)<sub>2</sub>D<sub>3</sub> decreased the percentage of high-grade dysplasia in vitamin D–deficient mice but had little to no effect in vitamin D–replete mice. No hypercalcemic toxicity was observed with this weekly dosing regimen. These data suggest that 1,25(OH)<sub>2</sub>D<sub>3</sub> supplementation among individuals with documented vitamin D deficiency may reduce premalignant changes in the bronchial epithelium. However, there was little benefit detected from 1,25(OH)<sub>2</sub>D<sub>3</sub> supplementation in vitamin D–replete mice.

If vitamin D plays a role in the prevention of lung cancer, one would predict that an inverse association exists between vitamin D exposure and risk of developing lung cancer. Indeed, multiple ecologic and epidemiologic studies have been conducted to ascertain this relationship. Variable associations have been found (for example, see Refs. [26–28]). However, two recent meta-analyses provide consistent evidence of protective effects of vitamin D. Zhang et al. tested the association between vitamin D and lung cancer risk using data from nine prospective cohort studies and three nested case–control studies [29]. They determined that the relative risk of lung cancer was 0.84 for high versus low vitamin D ( $P < .001$ ). However, serum 25(OH)D<sub>3</sub> concentrations were not reported, so the level of 25(OH)D<sub>3</sub> required for protection was not established. Chen et al. provided insight into this issue by performing a dose–response metaanalysis using data pooled from 10 prospective studies [30]. Their analysis identified a statistically significant 5% decrease in lung cancer risk for each 10 nmol/L increase in 25(OH)D<sub>3</sub>. The greatest reduction in lung cancer risk was detected at serum 25(OH)D<sub>3</sub> levels between 53 and 90 nmol/L. However, 25(OH)D<sub>3</sub> levels were measured at different laboratories and by different methods, which could have influenced the results. To overcome this limitation, Muller et al. examined the relationship between prediagnostic 25(OH)D<sub>3</sub> concentration (determined by gold standard LC-MS/MS assay in a single, DEQAS-certified laboratory) and lung cancer risk using >5300 cases and carefully matched controls selected from the Lung Cancer Cohort Consortium [31]. Participants were from Asia, Australia, Europe, and the United States, and 76% of the cohort was comprised of current- or former-smokers. No evidence was obtained for risk reduction by vitamin D.

Ultimately, randomized clinical trials will be required to definitively establish vitamin D effects on lung cancer risk. In this regard, multiple randomized, placebo-controlled trials of vitamin D<sub>3</sub> supplementation to prevent cancer have been recently completed including the Finnish Vitamin D Trial [32], the VITAL study [33],

**TABLE 90.1** The effect of vitamin D supplementation on cancer room.

Study	Baseline 25(OH)D <sub>3</sub> (ng/mL) <sup>a</sup>	Intervention	Average increase 25(OH)D <sub>3</sub> (ng/mL) <sup>a</sup>	HR vitamin D <sub>3</sub> versus placebo
Finnish trial	73.7	1,600 IU vitD <sub>3</sub> /day for 5 years	+9.4	1.14 (95% CI, 0.75–1.72; <i>P</i> = .55)
		3,200 IU vitD <sub>3</sub> /day for 5 years	+17.4	0.95 (95% CI, 0.61–1.47; <i>P</i> = .81)
Vital	77	2,000 IU vitD <sub>3</sub> /day for 5 years	+22	0.96 (95% CI, 0.88–1.06; <i>P</i> = .47)
ViDA	66.2	200,000 IU bolus then 100,000 IU monthly for median 3.3 y	+20	1.01 (95% CI, 0.81–1.25; <i>P</i> = .95)

HR, hazard ratio; IU, international units.

and the ViDA study [34]. All three studies focused on older adults. Participants were enrolled regardless of baseline vitamin D status. Summary details for each trial are provided in Table 90.1. Supplementation was consistently effective at increasing serum 25(OH)D<sub>3</sub> but did not reduce cancer incidence in the overall study populations (see Hazard Ratios, Table 90.1). However, protective effects were observed in a specific subset of VITAL participants: Vitamin D<sub>3</sub> supplementation was associated with a significant decrease in total cancers but only among individuals with normal body mass index [33]. This observation supports the idea that demographic factors such as obesity modify response to vitamin D<sub>3</sub> supplementation. No information about lung cancer incidence in placebo versus supplementation arms was reported in any of the trials. Thus, the impact of intervention specifically with regard to lung cancer risk remains undefined.

#### 4. The role of vitamin D in management of early-stage lung cancer

In addition to the potential role of vitamin D in slowing the development of lung cancer described above, several epidemiologic studies implicate vitamin D in controlling growth of established lung cancers. The first evidence that vitamin D status may play a role in established disease came in 2005, when an association between season of lung cancer resection as well as vitamin D intake and outcomes in early-stage NSCLC was reported [35]. Patients who underwent surgery

during summer months and had high vitamin D intake had improved overall and recurrence-free survival (RFS) compared with patients who had surgery during the winter with the lowest vitamin D intake [35]. Zhou et al. subsequently measured circulating 25(OH)D<sub>3</sub> in relation to outcomes using the same cohort of patients diagnosed with early-stage NSCLC [36]. More than 50% of subjects were classified as vitamin D<sub>3</sub>-deficient. Among patients with stage IB-IIIB NSCLC, those with the highest 25(OH)D<sub>3</sub> levels ( $\geq 21.6$  ng/mL) had significantly better RFS and overall survival (OS) than those with the lowest 25(OH)D<sub>3</sub> levels ( $< 10.2$  ng/mL).

Quite excitingly, protective effects of vitamin D<sub>3</sub> supplementation among patients with early-stage NSCLC have now also been observed in a prospective, randomized, placebo-controlled trial [37]. Patients who underwent surgery for NSCLC were randomized to receive placebo (*n* = 78) or 1200 IU vitamin D<sub>3</sub>/d (*n* = 77) for 1 year. The vitamin D<sub>3</sub> dose selected based on prior studies by group in Parkinson's disease. Patients (the majority of which had LUAD) received appropriate chemotherapy based on their diagnosis. Supplementation was effective. The average serum 25(OH)D<sub>3</sub> concentration in the supplemented group went from 21 to 39 ng/mL, whereas little change was observed in the group that received placebo. In the overall study cohort, no effect of supplementation on either RFS or OS was found. However, a significant effect was found within the subset of patients who had LUAD and were vitamin D deficient ( $< 20$  ng/mL) at baseline. RFS was 50% for placebo and 86% for the supplemented group (*P* = .04). OS was 48% for placebo and 91% for supplemented group (*P* = .02). A major conclusion from this trial was that vitamin D<sub>3</sub> supplementation is not likely to improve outcomes for all patients. Rather, specific patients (those with LUAD who are vitamin D deficient) will derive benefit. It is important to note that this trial was conducted in Japan, where *EGFR* mutations represent the predominate oncogenic driver of LUAD (44% of cases harbor activating mutations in *EGFR*). Results may portend a better effect of vitamin D specifically in *EGFR* mutant NSCLC, although this remains to be determined.

#### 5. The role of vitamin D in the management of advanced lung cancer

Owing to major discoveries in the field of lung cancer biology, advanced lung cancer standard of care has undergone a dramatic transformation in the recent decade. For many patients, targeted therapies and immune checkpoint inhibitors have replaced traditional cytotoxic chemotherapeutics. In this section, we will

provide some insights into the evolving role of vitamin D in the setting of this novel treatment paradigm.

### 5.1 *EGFR* mutations (mt) mark a subset of advanced LUAD that are vitamin D responsive

Although vitamin D signaling capacity and its potential antitumor activity in the lung may be dictated by tumor mutation profile, investigations into the role of vitamin D in lung cancer that were conducted before the advances of personalized medicine generally did not take into consideration tumor-specific genetic alterations. As genotype-matched therapies are increasingly used in contemporary management of advanced lung cancer, prognostic value of vitamin D status in defined molecular subtypes of lung cancer has come into the spotlight.

Several studies investigated VDR expression and antiproliferative effects of  $1,25(\text{OH})_2\text{D}_3$  in distinct molecular subclasses of NSCLC [38–40]. Cell lines were selected, which harbored mutually exclusive activating mutations in either the *KRAS* (A549, 128-88T) or *EGFR* genes (HCC827, H1975). Activating *EGFR* mutations are more frequently observed in females and non-smokers, whereas oncogenic *KRAS* mutations are more frequent in males and are associated with smoking [41]. Intriguingly, *KRAS* mutant lines expressed VDR at lower levels than the *EGFR* mutant cell lines. *EGFR* mutant cell lines displayed greater induction of VDR target genes and greater susceptibility to  $1,25(\text{OH})_2\text{D}_3$ -mediated growth inhibition than *KRAS* mutant cell lines. Similarly, PRI-2191, a potent VDR agonist, exerted higher antiproliferative activity and cell cycle arrest in *EGFR* mutant versus *KRAS* mutant lung cancer cells [42].

To determine whether *EGFR* mutant NSCLC cells were vulnerable to vitamin D-mediated growth inhibition in vivo, Verone-Boyle et al. fed mice bearing HCC827 subcutaneous xenografts research diets that varied in vitamin  $\text{D}_3$  content (100 IU–10,000 IU vitamin  $\text{D}_3$ /kg diet) [43]. Tumor growth (volume distribution and growth rate) was reduced significantly in mice that were fed the high dose 10,000 IU vitamin  $\text{D}_3$ /kg diet versus the low dose 100 IU vitamin  $\text{D}_3$ /kg diet. Verone-Boyle further demonstrated that VDR protein is expressed at detectable levels in 18/18 primary human lung tumors that harbor activating mutations in the *EGFR* gene [43]. A recent report demonstrated that circulating levels of  $25(\text{OH})\text{D}_3$  of  $>30$  ng/mL were predictive of a longer progression free survival in advanced NSCLC patients whose tumors harbored activating mutations in the *EGFR* gene (and received erlotinib), but not in those whose tumors were *KRAS* mutant (and received

cytotoxic chemotherapy) [44]. Oncogenic *KRAS* alterations are reported to be at least twice as frequent as *EGFR* mutations in lung cancer patients within the United States [45,46]. Consequently, prognostic value of vitamin D status may not be evident in molecularly nonselected cohorts, where a large fraction of patients is likely to have vitamin D–refractory *KRAS*-mutant tumors.

It is not yet known why *EGFR* and *KRAS* mutant NSCLC cells differ in VDR expression and  $1,25(\text{OH})_2\text{D}_3$  sensitivity. Zhang et al. hypothesized that mutation-related differences occur because *KRAS* and *EGFR* somatic alterations are differentially associated with smoking [38]. It is known that cigarette smoke exposure stimulates DNA hypermethylation and gene silencing [47–49] and that the VDR locus is subject to epigenetic control [50]. In light of this information, it seems possible that prior smoke exposure resulted in hypermethylation and long-term silencing of the VDR promoter specifically in *KRAS* mutant NSCLC cells. One could further predict that NSCLC cell lines derived from never-smokers and light smokers are more likely to express VDR and respond to  $1,25(\text{OH})_2\text{D}_3$  than NSCLC cell lines derived from smokers. This appears to be the case: H2228 (donor was nonsmoker), H3122 (harbors ELM4-*ALK* translocation associated with never or light smoking status), HCC827 (harbors *EGFR* mutation associated with never or light smoking status), and H2347 (donor was nonsmoker) cells were all tested for vitamin D sensitivity as part of larger NSCLC cell line panels [40,51,52]. In each study, the “nonsmoker” cell lines rank among the most sensitive to vitamin D–mediated growth inhibition. Cumulatively, these data imply that never or light smoking status, *EGFR* gene mutations, or *ALK* translocations may be used to identify those NSCLC patients who are likely to derive benefit from vitamin D supplementation.

### 5.2 24-Hydroxylase, encoded by the *CYP24A1* gene, has adverse effects in LUAD

In addition to high levels of VDR, lung tumor models that are intrinsically responsive to vitamin D express low levels of *CYP24A1*. *CYP24A1* encodes 24-hydroxylase, the primary enzyme responsible for catabolic inactivation of  $1,25(\text{OH})_2\text{D}_3$  [53]. *CYP24A1* expression is increased by  $1,25(\text{OH})_2\text{D}_3$  in normal target tissues including kidney, colon, intestine, and bone [54–56]. Inactivation of either VDR or *CYP24A1* (via inherited mutations or molecular approaches) results in elevated blood levels of  $1,25(\text{OH})_2\text{D}_3$ , indicating that VDR-dependent activation of *CYP24A1* is required for efficient  $1,25(\text{OH})_2\text{D}_3$  catabolism by normal tissues [57–60]. Physiologically, *CYP24A1* induction by

1,25(OH)<sub>2</sub>D<sub>3</sub> attenuates its own actions and prevents accumulation of toxic doses of the hormone.

*CYP24A1* is also expressed in lung cancer, where it promotes 1,25(OH)<sub>2</sub>D<sub>3</sub> catabolism and loss of antitumor activity. The expression of *CYP24A1* in lung cancer cells was first described in 1999 [61]. Shortly thereafter, it was demonstrated that *CYP24A1* mRNA and 24-hydroxylase are overexpressed in primary human lung tumors [62–64]. Shiratsuchi and colleagues reported a direct correlation between *CYP24A1* levels and tumor cell proliferation rates in vitro and in vivo [65]. In patients diagnosed with early-stage LUAD, *CYP24A1* mRNA expression is independently prognostic of survival: 5-year survival rates are 81% in individuals whose tumors express low levels of *CYP24A1* and 42% for those with high *CYP24A1* expression [64]. Studies conducted in preclinical models of lung cancer revealed that the oncogenic potential of *CYP24A1* is not only due to its function as a vitamin D degrader but also linked to its noncatalytic activity [66]. *CYP24A1* was shown to promote cell cycle progression by direct inhibition of APC, a ubiquitin ligase, critical for control of cell cycle.

It is generally agreed on that *KRAS*-mutant tumors, including those originating in lung, are not only deficient in VDR, but also express high levels of *CYP24A1* [38,43,67]. The VDR<sup>low</sup> *CYP24A1*<sup>high</sup> phenotype of *KRAS*-mutant lung tumors may be responsible for their apparent lack of response to vitamin D.

### 5.3 Combining vitamin D with targeted therapeutics

A growing body of evidence suggests that future investigations of vitamin D in the context of advanced lung cancer may be best focused on the most responsive subtypes and in combination with other therapeutic agents. *EGFR*-mutant NSCLC is emerging as a primary candidate for evaluation of vitamin D–based combination treatment strategies. Patients diagnosed with *EGFR*-mutant lung cancer are routinely treated with one of the FDA-approved small molecule *EGFR* tyrosine kinase inhibitors (*EGFR* TKIs), erlotinib, gefitinib, or osimertinib. When applied, *EGFR* TKIs suppress *EGFR* phosphorylation and downstream activation of proliferative/prosurvival pathways involving MAPK, Akt, and STAT3. Initial tumor response to *EGFR* TKIs is frequently followed by development of treatment-tolerant and eventually treatment-resistant disease [68]. Some of these therapy-refractory tumors exhibit features of epithelial to mesenchymal transition (EMT) [69–72].

EMT is a process that drives epithelial cells to adopt a more invasive mesenchymal phenotype. Molecularly, EMT involves downregulation of epithelial marker

*CDH1* (encodes E-cadherin) and upregulation of mesenchymal markers, including vimentin (VIM), SNAIL, and ZEB1. In lung cancer models, EMT confers resistance to key treatment modalities including radiation [73,74], chemotherapy [75], and targeted therapeutics [69,76,77]. It has been shown that 1,25(OH)<sub>2</sub>D<sub>3</sub> opposes TGFβ-driven induction of EMT in lung epithelial cells, lung fibroblasts, and lung cancer cells [40,78]. Specifically, 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment decreases TGFβ induction of an EMT gene expression profile, cell migration, and cell invasion. In preclinical *EGFR*-mutant, EMT-driven models of *EGFR* TKI tolerance, 1,25(OH)<sub>2</sub>D<sub>3</sub> not only restores expression of epithelial markers, but also promotes cell cycle arrest and improves sensitivity to *EGFR* TKIs [44].

EMT appears to be a common mechanism underlying emergence of lung cancer refractory to targeted therapies. NSCLC patients whose tumors are positive for rearrangement of the anaplastic lymphoma kinase (ALK) follow similar clinical course of disease progression in response to ALK TKI treatment to that of *EGFR*-TKI treated patients: initial tumor regression is usually followed by relapse under targeted therapy. A fraction of ALK-positive tumors with acquired TKI resistance undergoes morphological and molecular changes consistent with EMT [79,80]. Since the recent report suggests that the ability of vitamin D to promote sensitivity to targeted therapeutics may be linked to its proepithelial properties [44], vitamin D–based combination treatments may be beneficial for the patients with EMT-associated resistance to ALK TKI. This hypothesis requires further investigation.

Although the idea of exploiting vitamin D signaling to overcome EMT-associated TKI failure is intriguing, several studies demonstrate that reciprocal regulation occurs between 1,25(OH)<sub>2</sub>D<sub>3</sub> and EMT mediators (reviewed in Ref. [81]). Thus, while 1,25(OH)<sub>2</sub>D<sub>3</sub> signaling opposes EMT, promesenchymal transcription factors such as SNAIL repress VDR expression [82,83]. The direct ability of promesenchymal transcription factors to repress VDR in NSCLC cells has not been tested. However, analysis of gene expression profiles from 75 NSCLC cell lines identifies a statistically significant inverse correlation between VDR and *ZEB1* [40]. Nevertheless, it has been demonstrated that vitamin D signaling axis remains intact and functional in *EGFR* mutant NSCLCs that underwent EMT while treated with *EGFR* TKIs [44]. Therefore, the opportunity exists to employ vitamin D–based therapeutics in the setting of progressive disease.

Another consistent mechanism that allows lung tumors to escape targeted therapeutics is MET amplification [14]. MET is a receptor tyrosine kinase situated upstream of PI3K/AKT and other oncogenic signaling cascades [14]. MET is activated by a pleiotropic factor

**TABLE 90.2** Stage- and context-specific actions of vitamin D in NSCLC.

Disease stage/ type	Treatment modality	Comment
Early stage	Surgery	Vitamin D3 supplementation improves RFS and OS among individuals with LUAD who are vitamin D deficient.
Advanced KRAS mt LUAD	Cytotoxic chemotherapy	Vitamin D3 metabolites unlikely to be effective. Tumors tend to be VDR low/CYP24A1 high and intrinsically refractory to vitamin D.
Advanced KRAS mt LUAD	Immune checkpoint blockade	Vitamin D3 metabolites may be effective. T cells express VDR. Vitamin D may reduce expression of immune checkpoints on T cells, prevent their exhaustion, and increase antitumor immunity.
Advanced EGFR mt LUAD	EGFR TKIs	Vitamin D3 metabolites may be effective. Tumors tend to express VDR. VDR signaling maintains tumor cells in an epithelial state in which they are sensitive to EGFR TKIs.

HGF and promotes survival, proliferation, and motility of tumor cells. Early studies conducted in human lung fibroblast cell lines reported modest but significant inhibition of HGF production in response to 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment [84]. Therefore, vitamin D may promote sensitivity or delay resistance to MET TKIs by modifying MET/HGF signaling.

Molecular profiling of lung tumors led to a fundamental shift in treatment paradigm of this deadly malignancy. Genotype-matched medicine is now a standard of care for many patients diagnosed with advanced lung cancer. Today, we recognize that treatment selection for these patients is best guided by targeting tumor-specific molecular alterations. Similarly, an accumulating body of evidence advocates for variable response to vitamin D in different tumor genotypes (Table 90.2). Thus, future research aimed to determine clinical utility of vitamin D in lung cancer can only benefit from careful refinement of tumor subsets considered for studies.

#### 5.4 Combining vitamin D with immunotherapeutics

For a select patient population diagnosed with NSCLC, immunotherapy has become a standard of care (Fig. 90.2). Several immunomodulatory agents approved for the use in advanced lung cancer target

the interaction between programmed cell death receptor 1 (PD1) on the surface of T cells and programmed death ligand 1 (PD-L1) expressed by the tumor cells. This interaction suppresses tumor reactivity of T cells, allowing cancer cells to expand and metastasize [85]. Tumor expression of PD-L1 is one of the biomarkers used to select patients who are likely to benefit from one of the immunotherapeutic agents [86]. Vitamin D has been shown to induce expression of PD-L1 in myeloid and epithelial cells [87]. Hence, combining vitamin D with immune checkpoint inhibitors may augment the efficacy of this class of drugs. Efficacy data should be available soon, as the effect of vitamin D<sub>3</sub> supplementation on treatment outcomes among patients with advanced cancer who receive immunotherapy is under active clinical evaluation (PROVIDENCE study) [88].

One could argue that potentially elevated levels of PD-L1 in response to vitamin D treatment may cause protumorigenic effects in patients who are not treated with immunotherapies. A recently published study by Li et al. [20] alleviates this concern. Patients with advanced NSCLC received chemotherapy with docetaxel followed by rocaltrol (0.5–2.0 µg/day) for 3 weeks. Controls received docetaxel alone. Blood was collected pretreatment and at conclusion of therapy for analysis of T cell biomarkers. At baseline, serum levels of 25(OH)D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub> were negatively correlated with immune checkpoints PD-1, TIGIT, and Tim-3 but positively correlated with expression of costimulatory molecule, CD28. Rocaltrol administration resulted in a significant increase in serum 1,25(OH)<sub>2</sub>D<sub>3</sub> and a significant decrease in PD-1, TIGIT, and Tim-3. Chromatin immunoprecipitation experiments showed that VDR binds to the promoters of these genes. In vitro treatment of T cells with 1,25(OH)<sub>2</sub>D<sub>3</sub> led to enhanced killing of tumor cells. In total, findings are consistent with a role for 1,25(OH)<sub>2</sub>D<sub>3</sub> (as a single agent) in directly repressing expression of immune checkpoints on T cells and promoting antitumor immunity.

It should be noted here that the efficacy of immune checkpoint inhibitors in *KRAS* mutant LUAD is well established [89]. Although tumor-intrinsic vitamin D signaling may not be effective in such tumors as discussed in Section VI A, the ability of vitamin D to regulate T cell function may nonetheless be an important determinant of treatment efficacy. Thus, one must consider not only the tumor genotype but also the treatment type in ascertaining the potential of vitamin D to influence lung cancer outcomes (Table 90.2).

Another layer of complexity relates to possible effects of vitamin D on drug metabolism. Nivolumab is one of the most commonly used immune checkpoint inhibitors for the treatment of advanced lung cancer. As with many pharmacological agents, nivolumab exposure directly correlates with tumor response [90]. Intriguingly,

patients treated with nivolumab whose circulating 25(OH)D<sub>3</sub> is below 10 ng/mL have been reported to have a significantly lower serum nivolumab concentration than those whose circulating 25(OH)D<sub>3</sub> is above 10 ng/mL [91]. This finding highlights the potential role of vitamin D in drug metabolism and needs to be validated by larger studies.

## 6. Strategies to maximize vitamin D signaling in lung cancer

To realize antitumorigenic potential of 1,25(OH)<sub>2</sub>D<sub>3</sub>, supraphysiological concentrations may be required, which leads to hypercalcemic toxicity in vivo. To address this issue, one of the following routes can be taken. Since tumor activity of vitamin D is known to be inversely correlated with expression of *CYP24A1*, its direct inhibition may increase tumor exposure to active metabolite of vitamin D and promote its antiproliferative activity. Alternatively, structural analogs of vitamin D with reduced calcemic activity can be used to minimize toxicity. Finally, novel formulations and routes of administration could limit systemic exposure and maximize vitamin D delivery directly to the tumor cells. In this section, we will highlight current efforts to maximize vitamin D activity in lung cancer.

A variety of vitamin D structural analogs have been synthesized and used in preclinical and clinical studies. Some of the compounds have reduced calcemic side effects and are successfully used in the clinic to treat psoriasis, renal disease, and secondary hyperparathyroidism [92]. While the use of vitamin D analogs has been widely investigated in malignancies of breast, colon, prostate, pancreas, and other sites, only few studies examined their effects on lung cancer pathogenesis.

Maxacalcitol has antiproliferative activity in LSCC cells in vitro, with significant growth suppression detected at concentrations as low as 10<sup>-9</sup>M. A similar magnitude of growth inhibition was achieved with 10<sup>-8</sup>M 1,25(OH)<sub>2</sub>D<sub>3</sub> [93]. Antiproliferative and antimetastatic activity of maxacalcitol was also demonstrated using the Lewis lung carcinoma model. In vitro, maxacalcitol inhibited production of MMP2, MMP9, and VEGF. Furthermore, mice injected intravenously with Lewis lung carcinoma cells and then treated with maxacalcitol developed fewer lung lesions while maintaining normal serum calcium levels and body weight. In contrast, a 10%–15% decrease in body weight and increase in serum calcium concentration were observed in 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated mice [94].

PRI2205, another less calcemic vitamin D analog, exhibited modest antiproliferative activity in A549 LUAD cells. When tested in the mouse Lewis lung

carcinoma xenograft model, PRI2205 had tumor-suppressive effects similar in magnitude to 1,25(OH)<sub>2</sub>D<sub>3</sub>, but with a significant reduction in toxicity and calcemic activity [95]. The outcome of combining PRI2205 with imatinib mesylate (Gleevec) was investigated in the A549 mouse tumor xenograft model, but with limited success. Although the combination of vitamin D analog and tyrosine kinase inhibitor slowed down growth of the tumors by ~50%, body weight reduction by ~15% was also noted, indicating moderate toxicity [96].

Seocalcitol (EB1089) enhanced response to radiation in H460 and A549 NSCLC cells [97]. The reported mechanism of action in irradiated cells involves a seocalcitol-dependent switch from cytoprotective to cytostatic autophagy, accompanied by cell cycle arrest. The radiosensitizing effect of seocalcitol was dependent on VDR and functional TP53 and was not observed in normal bronchioepithelial cells or cardiomyocytes, indicating specificity toward cancer cells [97]. These compelling results are yet to be replicated in vivo.

As discussed earlier, vitamin D antitumor activity is limited by high local levels of *CYP24A1*. This observation led to a series of studies to determine the effects of 24-hydroxylase activity on 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated transcription and antiproliferative activity in lung cancer. H292 cells expressing high levels VDR were treated with 1,25(OH)<sub>2</sub>D<sub>3</sub> or 1,25(OH)<sub>2</sub>D<sub>3</sub> plus CTA091 and subjected to microarray analysis [98] and growth assays [63]. CTA091 is a selective inhibitor of 24-hydroxylase [99]. CTA091 inhibits 24-hydroxylase at low nanomolar concentrations and does not itself regulate gene expression through the VDR [100]. CTA091 globally potentiated the effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> on gene expression [98]. In growth assays, CTA091 had no single agent activity. However, it potentiated the antiproliferative effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> [63]. The ability of CTA091 to block 1,25(OH)<sub>2</sub>D<sub>3</sub> catabolism in H292 lung tumor xenografts has also been investigated: [101] CTA091 administration resulted in a 1.6-fold increase in plasma 1,25(OH)<sub>2</sub>D<sub>3</sub> and a 2.6-fold increase in intratumor levels of 1,25(OH)<sub>2</sub>D<sub>3</sub>. Compartmental modeling of 1,25(OH)<sub>2</sub>D<sub>3</sub> concentration versus time data confirmed that 1,25(OH)<sub>2</sub>D<sub>3</sub> was eliminated from plasma and tumor; CTA091 reduced the elimination from both compartments, and the effect of CTA091 on tumor exposure was greater than its effect on plasma. In total, these data indicate that 24-hydroxylase restricts 1,25(OH)<sub>2</sub>D<sub>3</sub> levels and signaling in lung cancer cells, and that 24-hydroxylase selective inhibitors (such as CTA091) may be used to enhance the anticancer effects of 1,25(OH)<sub>2</sub>D<sub>3</sub>.

Most common routes of vitamin D administration that are expected to result in elevated lung tissue exposure include dietary supplementation and IV injection of

active metabolites. While dietary vitamin D is generally safe, pharmacological concentrations in the lung are not likely to be reached. On the other hand, administering  $1,25(\text{OH})_2\text{D}_3$  via IV route is predicted to achieve higher levels of the active metabolite in the lung, but systemic exposure that may lead to hypercalcemia is also more likely to occur. Alternatively, high local concentrations of  $1,25(\text{OH})_2\text{D}_3$  in the lung may be achieved by intrapulmonary administration. Horiguchi and colleagues delivered a range of  $1,25(\text{OH})_2\text{D}_3$  doses (0–10  $\mu\text{g}/\text{kg}$ ) twice a week for 3 weeks directly into the airways of mice [102]. None of the dosing regimens resulted in significant loss of body weight. Bianchi et al. exposed mice to aerosolized  $1,25(\text{OH})_2\text{D}_3$  at 10ng/1 mL or saline for 10 min every other day for the duration of the study [103]. No change in body weight was reported. Furthermore, mice treated with aerosolized  $1,25(\text{OH})_2\text{D}_3$  developed significantly fewer lung tumor nodules derived from intravenous injection of colon cancer cells. Although the levels of  $1,25(\text{OH})_2\text{D}_3$  in the lung tissue and in the circulation were not evaluated in the aforementioned studies, no significant change in body weight was observed in all animals, suggesting lack of hypercalcemia-related toxicity. Detailed studies of tissue distribution of  $1,25(\text{OH})_2\text{D}_3$  following intrapulmonary administration are needed to evaluate clinical relevance and potential advantages of this vitamin D delivery method.

Finally, alternative formulations of vitamin D can be used to facilitate its delivery directly to tumor cells while reducing its availability to normal tissues. Nanoparticles are a novel platform for drug encapsulation that promises tumor delivery of its cargo with enhanced precision [104,105]. Hence, nanosystems may be particularly suitable for the use with vitamin D-based combination treatments. Few studies looked into employing this approach to deliver vitamin D to the tumors of the lung. In vitro, EGFR-targeted lipid-based nanoparticle (EGFR-LP) was used to codeliver  $1,25(\text{OH})_2\text{D}_3$  and 24-hydroxylase inhibitor CTA091 to EGFR-mutant TKI-resistant lung cancer cells [106]. Nanoparticles were taken up by the cells and induced greater vitamin D-dependent transcriptional response than the combination of free  $1,25(\text{OH})_2\text{D}_3$  and CTA091 at identical concentrations. Additionally, EGFR-LP-CTA091-VD promoted anticlonogenic activity of EGFR TKI erlotinib and increased expression of epithelial marker E-cadherin in the EMT-associated model of resistance to EGFR TKIs. As discussed before, CTA091 has been shown to augment antitumor activity of vitamin D. However, administration of free CTA091 is expected to result in systemic inhibition of 24-hydroxylase and hypercalcemia [100]. Therefore, the use of nanocarrier to encapsulate  $1,25(\text{OH})_2\text{D}_3$  and CTA091 is a compelling option to maximize

therapeutic efficacy of vitamin D. Follow-up in vivo studies are needed to evaluate the safety and efficacy of this novel vitamin D formulation. Although studies of vitamin D containing nanoparticles conducted in animal lung tumor models are lacking, in a murine model of breast cancer, pH-responsive nanoparticles carrying  $1,25(\text{OH})_2\text{D}_3$  in combination with paclitaxel (PCDMs) were found to be less calcemic than treatment with free  $1,25(\text{OH})_2\text{D}_3$  plus paclitaxel [107]. Significant increase in tumor accumulation of  $1,25(\text{OH})_2\text{D}_3$  in mice treated with nanomedicine versus free drugs was reported. This was accompanied by reduction in primary tumor volume and number of metastatic nodules in the lungs of the animals. The aforementioned results provide support for further investigation of safety and clinical utility of vitamin D-based nanomedicine for the treatment of lung cancer.

## 7. Conclusions

Promising signs of vitamin D activity in discreet subsets of patients with lung cancer are emerging. However, the full potential of vitamin D has yet to be realized. Precision clinical trials in which vitamin D supplementation is tested in combination with genotype-directed therapies among individuals with baseline deficiency are urgently needed. Precision trials should include tailored correlative studies, so that the underlying mechanisms (such as reversal of EMT or improved T cell effector function) can be confirmed. Parallel advances in the development of novel  $1,25(\text{OH})_2\text{D}_3$  analogs and  $1,25(\text{OH})_2\text{D}_3$  delivery systems are occurring. These formulations have potential to provide improved safety and efficacy and open new avenues of investigation in lung cancer.

## 8. Summary points

1. Preclinical studies demonstrate the ability of vitamin D to reduce the number and progression of premalignant airway epithelial lesions. Although no consistent association between vitamin D status and lung cancer risk has been established in the clinic, it appears that protective effect of vitamin D may be limited to populations with specific demographic characteristics, such as smoking status and BMI.
2. Similarly, in the setting of established disease, vitamin D is unlikely to be universally beneficial for recurrence-free or overall survival of lung cancer patients. Rather, in line with a contemporary precision medicine approach, vitamin D supplementation should be targeted to the most

responsive subtypes of lung tumors, including those with EGFR mutations.

3. Ongoing development of less calcemic vitamin D formulations and delivery systems may provide a safer way to implement high-dose vitamin D-based therapies for lung cancer treatment.

## Vitamin D and prostate cancer

*Larisa Nonn<sup>1</sup>, Kirsten Krieger<sup>1</sup>, Clayton Yates<sup>2</sup> and Moray J. Campbell<sup>3</sup>*

<sup>1</sup>Department of Pathology, University of Illinois at Chicago, Chicago, IL, United States <sup>2</sup>Department of Biology and Center for Cancer Research, Tuskegee University, Tuskegee, AL, United States <sup>3</sup>The College of Pharmacy, The Ohio State University, OH, Columbus, United States

### OBJECTIVES

- Present the key data on prostate cancer incidence, mortality, and associations with 25-hydroxyvitamin D status.
- Discuss relevance of the dual disparities in African American men for prostate cancer and 25-hydroxyvitamin status.
- Present experimental evidence and clinical trials for a role for vitamin D metabolites in prevention and treatment of aggressive PCa.
- Describe genomic actions of vitamin D metabolites in prostate cells.
- Summarize current state of the field and discuss future directions.

### 1. Introduction: prostate cancer is a heterogeneous disease

In the United States, prostate cancer (PCa) is the most commonly diagnosed cancer in men with an estimated 268,490 new cases for 2022 (Cancer Facts & Figures 2022, American Cancer Society (ACS)). Globally, in 2020, approximately 1.4 million cases were recorded, and 375,000 deaths were attributed to PCa [1]. Within the United States, PCa has a 5-year survival rate of 98%, and this cancer remains the second leading cause of cancer deaths in men, with 34,500 deaths estimated for 2022. As these data illustrate, although PCa diagnosis is quite common worldwide, about 12% of US patients

ultimately experience a lethal form of PCa, whereas globally, mortality rises to 26%. These data indicate that the course of diagnosis and impact of treatment have divergent outcomes. The diversity of these outcomes includes the range of healthcare provision in different countries and the contribution of genomic ancestry [2].

PCa arises from a spectrum of molecular drivers that include those identified in precancerous conditions such as high-grade prostatic intraepithelial neoplasia (HGPIN). Most commonly, PCa is diagnosed when the cancer is localized to the prostate gland. Progression to invasive and metastatic disease can occur when patients experience therapy failure in response to curative attempts with either surgical or radiation approaches for localized disease. This invasive disease is then treated with systemic therapies, and ultimately androgen deprivation therapy (ADT) approaches, which are initially highly effective, but also have, ultimately, a high failure rate. This ADT-resistant form of PCa is typified by tissue plasticity and the development of so-called androgen-independent states. This final disease state is frequently lethal.

In parallel to this spectrum of disease states, with potentially differing therapeutic vulnerabilities, the pathological scoring system for PCa has changed over the years. Initially, grading relied on the Gleason grade for defining tumors; the Gleason grade characterized the aggressiveness of the tumor [3]. Thus, tumor foci with a Gleason grade  $\leq 3$  were characterized as low grade and those  $\geq 4$  as high grade. Subsequently, the concept of the Gleason score arose, as the sum of most common foci, and currently, this has been replaced by the Grade Group, which combines Gleason score with stage [4].

Nonetheless, uncertainties remain in prognosis despite these improvements in diagnosis accuracy. It remains unclear which men will experience treatment failure following curative attempts for localized disease. Similarly, in men with advanced disease, it is unclear which patients will experience a sustained tumor response toward to ADT, versus those for whom their tumor will rapidly progress.

The challenges of accurate PCa prognosis are amplified by a significant racial health disparity in which African American (AA) patients experience a more aggressive cancer that occurs at a younger age than in European American (EA) counterparts [5]; AA men experience a two-times risk of aggressive and lethal disease compared with their EA counterparts [6]. Indeed, AA men have higher prostate-specific antigen (PSA) [7] and larger tumor volume [8] compared with EA counterparts. Genomic ancestry underpins this disparity whereby genetic [9–11] and epigenetic [12–17] factors combine with biopsychosocial processes to drive AA PCa. For example, the incidence of *TMPRSS2* and *ETS* fusion genes [18,19] is common in EA PCa, but infrequent in AA counterparts [15,20,21]. As a result, the reasons for these disparities are multifactorial, likely involving biological factors as well as differences in lifestyle, screening, treatment, and quality of care in some cases. However, when controlling for socioeconomic factors and access to healthcare, the disparity persists with AA men presenting with PCa at a younger age and with disease that is more aggressive [22].

Set against this backdrop of a complex, heterogeneous, and evolving cancer, which is heavily impacted by genomic ancestry, a key challenge in the field of vitamin D research has been to identify in what PCa grade and progression context would vitamin D-centered therapeutic options be most effective (Fig. 91.1).

## 2. Epidemiologic associations between prostate cancer and vitamin D metabolites

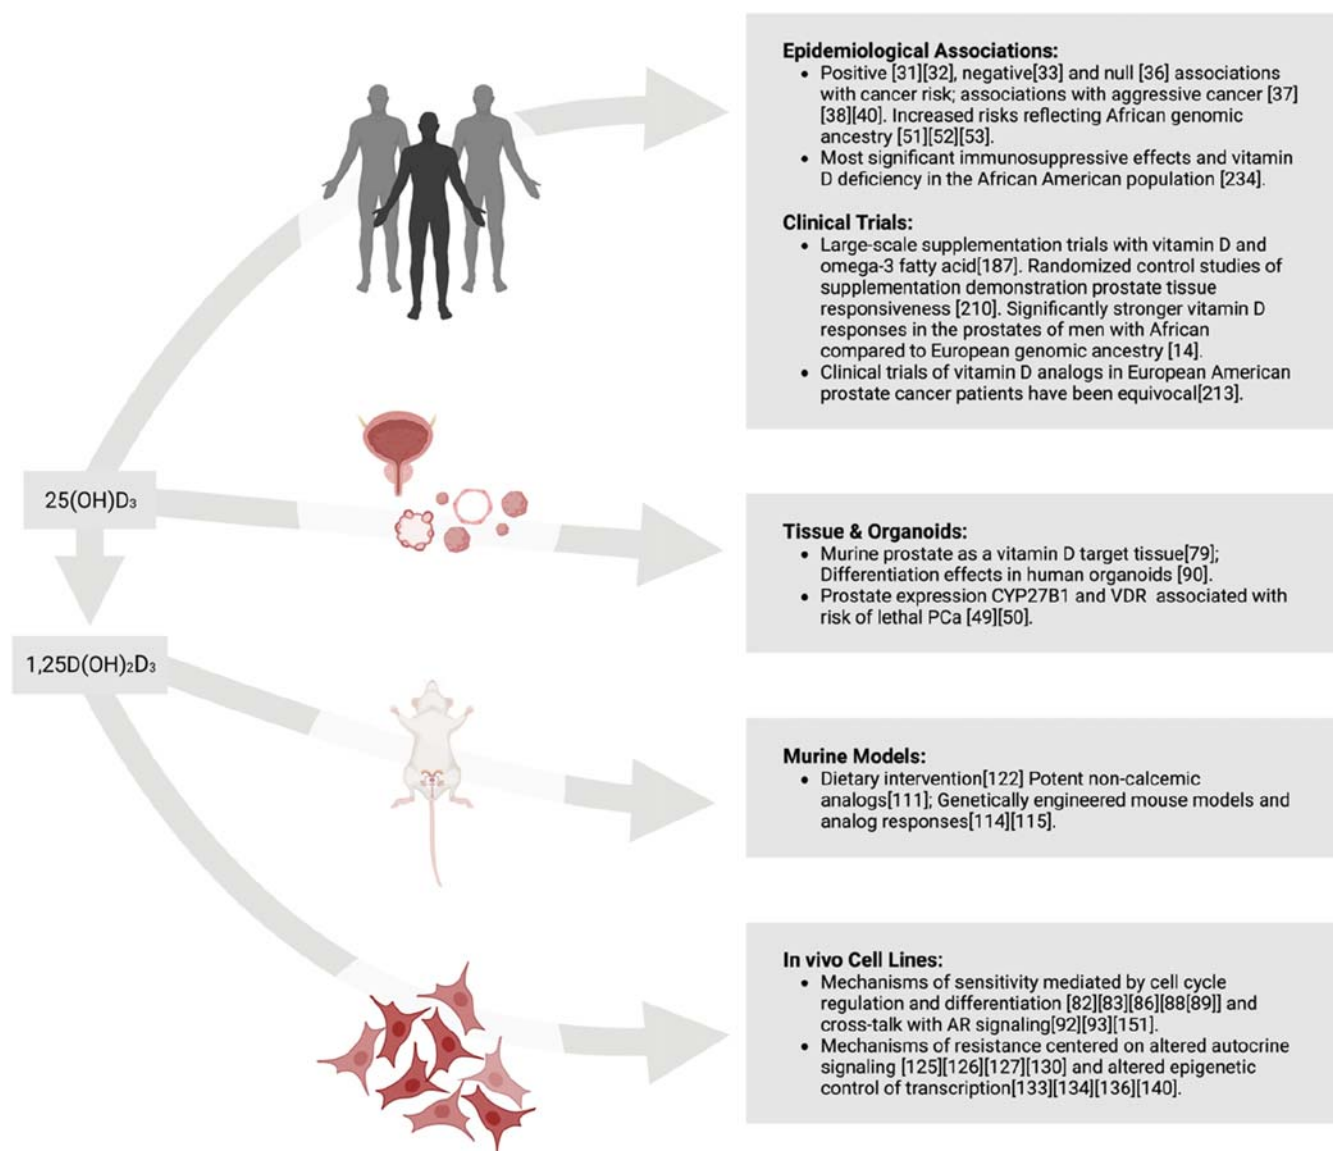

Epidemiological studies across several decades have analyzed blood levels of vitamin D metabolites and tested their associations with PCa risk and mortality. These studies began in the 1980s led by Cedric Garland and coworkers, who were largely responsible for initiating the analyses between solar UVB exposure, serum 25-hydroxyvitamin D (25(OH)D<sub>3</sub>), and cancer incidence [23,24]. These initial studies, which focused on colon cancer, were the catalyst for this team [25] and others [26–29] to investigate these relationships in the context of PCa.

The majority of PCa studies examine 25(OH)D<sub>3</sub>, but some include 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D<sub>3</sub> or calcitriol) and disease risk. When considering overall

PCa incidence, the results are mixed with both positive [30–32], negative [33,34], significant, and null [35–37] associations all reported, and therefore, it can be hard to make an overall interpretation. However, given the high prevalence of indolent PCa, one can argue that the association with risk of aggressive PCa has more clinical relevance, and there is a need to define the genomic characteristics when 25(OH)D<sub>3</sub> appears protective.

Studies that examine relationship between 25(OH)D<sub>3</sub> status and aggressive or lethal PCa overwhelmingly support that 25(OH)D<sub>3</sub> deficiency increases risk. A 2008 metaanalysis of seven cohort studies found a protective 0.91 hazard ratio (HR) for each 20 nmol/L increase in circulating 25(OH)D<sub>3</sub> [38]. Similarly, a prospective study of 1260 PCa patients and 1331 controls revealed that high serum 25(OH)D<sub>3</sub> associated with 57% reduction in risk of lethal PCa, but had no association with overall PCa risk [39]. An observational study in 2014 of ~3200 PCa patients and controls showed that increased 25(OH)D<sub>3</sub> serum levels were significantly associated with the reduced risk or higher grade PCa [40]. Similarly, a 2015 study using a smaller cohort attempted to test the significance of the association between circulating 25(OH)D<sub>3</sub> and risk of lethal PCa and but failed to identify significant relationships [41]. Possible explanations for these varied results are simple chance given the modest protective effects identified, disease severity, genomic ancestry of patients, diagnosis procedures, screening practices, and factors relating to vitamin D receptor biology that modify these associations [41]. For example, levels of vitamin D-binding protein (DBP) may modify the association between 25(OH)D<sub>3</sub> and risk of aggressive/lethal PCa [42].

Secondary analyses in large cohorts have also supported a chemopreventive role for 25(OH)D<sub>3</sub>. In the large Selenium and vitamin E Cancer prevention Trial (SELECT) of ~35,000 men, Kristal et al. observed a U-shaped association between serum 25(OH)D<sub>3</sub> levels and PCa risk overall as well as risk of aggressive high-grade PCa (Gleason score ≥7) [43]. As expected, the AA patients in this cohort had significantly lower serum 25(OH)D<sub>3</sub> levels than their EA counterparts, but associations with PCa risk could not be established as the AA cohort was much smaller than the EA one. Prior to SELECT, there were several smaller observational studies that also reported a U-shaped association between 25(OH)D<sub>3</sub> concentrations and PCa incidence [44–46]. Grant et al. reviewed U-shaped associations and posited that adverse risks at the higher concentrations may be due to inclusion of patients with underlying cardiovascular diseases and/or underlying pathophysiological processes altered by 25(OH)D<sub>3</sub>-induced changes in the immune system [47].

**FIGURE 91.1** Summary of the approaches to studying the vitamin D receptor system in prostate cancer. Investigators have applied different strategies from both observational and clinical trials in humans, to tissue isolates, murine models, and cell lines to consider the function of the VDR, 25(OH)D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub> in the normal prostate and prostate cancer.

There are also significant associations between PCa risk and the expression of VDR-regulated genes. Epstein et al. showed that epidemiological studies of gene expression are unlikely to be biased by season of tissue collection as intraprostatic expression of vitamin D-regulated proteins (e.g., CYP27A1, CYP27B1, RXR $\alpha$ , CYP24A1) did not vary by season, in contrast circulating levels of vitamin D metabolites [48]. Such candidate gene studies can be challenging to undertake given the complex nature in which genes are regulated. However, it is interesting to note that low prostate expression of CYP27A1, a vitamin D-regulated gene, associated with higher risk of lethal PCa [49]. As well, tumor expression of the VDR protein itself within tumors

associated with reduced risk of lethal PCa with a striking HR of 0.17 in the Physicians Health Study and Health Professionals cohort [50].

The majority of epidemiological studies for PCa and vitamin D metabolites do not include racially diverse cohorts. However, those that do have shown that serum 25(OH)D<sub>3</sub> levels inversely associate with lethal PCa in AA men [51,52] and 25(OH)D<sub>3</sub> status predicted PCa biopsy outcomes [53]. Indeed, it has been suggested that only in AA men does the molar ratio of 25(OH)D<sub>3</sub>:1,25(OH)<sub>2</sub>D<sub>3</sub> associate with decreased risk of aggressive PCa [54].

Taken together, the epidemiological data consistently support an association between low circulating 25(OH)

D<sub>3</sub> and risk of aggressive/lethal PCa and that these associations appear to largest and most clinically impactful in AA men. However, these relationships are complex and reflect lifetime exposures, and controlling for life-style factors can significantly impact the strength of the relationships [55]. Larger studies may yield more refined thresholds for PCa risk as routine 25(OH)D<sub>3</sub> screening and supplementation have become more frequent in the past few decades, and indeed establish whether prostate-specific levels are most accurately established when based on genomic ancestry.

## 2.1 25-Hydroxyvitamin D status and the disparity of prostate cancer in men of African genomic ancestry

The importance of defining what is the correct 25(OH)D<sub>3</sub> status for prostate health, and how this varies by genomic ancestry and latitude, are key to determine how this signaling axis may prevent or reduce PCa risk. Reflecting the UVB-catalyzed synthesis of 25(OH)D<sub>3</sub>, skin melanin levels are a major predictor of 25(OH)D<sub>3</sub> deficiency [56]. Consequently, >90% of AA men have 25(OH)D<sub>3</sub> insufficiency according to current standards set by Hollis et al. [57,58], while 65% are considered deficient with serum 25(OH)D<sub>3</sub> levels below 20 ng/mL [59]. In comparison, ~60% of EA men have 25(OH)D<sub>3</sub> insufficiency, and only 20% are considered deficient [59]. Although the deficiency of 25(OH)D<sub>3</sub> in AA is undisputable, it is often considered a paradox, as at the population level the incidence of rickets or skeletomuscular disorders is not higher in the AA population. However, as discussed before, the threshold of 25(OH)D<sub>3</sub> concentrations for non-calcemic actions remains undetermined.

In regard to genomic ancestry and 25(OH)D<sub>3</sub> status, it is critical to discuss a highly publicized 2013 study by Powe et al., which demonstrated that AA men have lower circulating DBP; thus, although deficient in total 25(OH)D<sub>3</sub>, AA men have equivalent free-25(OH)D<sub>3</sub> [60]. However, it was quickly pointed out that this NEJM study utilized a monoclonal antibody ELISA, which has decreased affinity for Gc1F phenotype that is homozygous in >90s of African Americans, leading to underestimation of DBP in AA men [61,62]. Thus, throughout the chapter, we will include and highlight studies that examine genomic ancestry and/or utilize models from AA men.

## 3. The rationale to treat prostate cancer by targeting the VDR

Understanding the cellular impact of VDR signaling was profoundly catalyzed by studies in 1981 by Kay

Colston, led by David Feldman, who were the first to demonstrate that low nanomolar concentrations of 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited the in vitro proliferation of human melanoma cell lines [63,64]. This was both a pioneering and fortuitous discovery. This was pioneering because it encouraged researchers to consider the impact of 1,25(OH)<sub>2</sub>D<sub>3</sub> on other cell systems [65–68], and also helped to illuminate the association studies undertaken by the Cedric Garland and coworkers the year before in 1980. These studies were fortuitous as the cells were obtained from a group in an adjacent laboratory who just happened to provide human melanoma cell lines. Thus, the discovery that 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited the proliferation of cancer cells demonstrated that this seco-steroid hormone had functions in tissues that were not classical targets for the metabolism and deposition of calcium, and further this demonstrated the potential efficacy of 1,25(OH)<sub>2</sub>D<sub>3</sub> as an anticancer agent. It is interesting to note that this important work, and other analyses during the 1980s on 1,25(OH)<sub>2</sub>D<sub>3</sub> as an anticancer agent, preceded the cloning of the VDR in 1988 [69].

The importance of this work resonated with others who were examining other compounds that could induce cancer cell differentiation. For example, the impact of retinoids that target the retinoic acid receptors, a cousin of the VDR, was investigated to drive cell differentiation of HL60 leukemia cells [70]. In turn, these had studies led to the pharmacologic exploitation of all-*trans* retinoic acid in leukemia [71] and were the catalyst for the development of the concept of differentiation therapy [72–74]; all-*trans* retinoic acid remains a current clinical option in acute promyelocytic leukemia. It is within this context, therefore, that the potential for exploiting 1,25(OH)<sub>2</sub>D<sub>3</sub> as a potential differentiation agent was explored in a wide variety of cancer cell lines, including PCa, all major solid tumors and leukemia [75–77].

## 3.1 Effects of vitamin D and analogs in preclinical models of prostate

A large body of literature has investigated the cellular impacts of targeting the VDR by 1,25(OH)<sub>2</sub>D<sub>3</sub> and a number of pharmacological analogs [78]. An initial focus was to establish that the murine prostate was a possible vitamin D target tissue [79] and that prostate cancer cell lines expressed the VDR [80]. However, the first targeting of the VDR in human PCa cell lines was in 1993 and clearly established that while the three cell lines examined expressed comparable levels of VDR, there was no clear relationship to the cellular sensitivity toward 1,25(OH)<sub>2</sub>D<sub>3</sub>. For example, LNCaP and DU-145 cells expressed comparable amounts of VDR, but

although LNCaP was strongly growth inhibited by  $1,25(\text{OH})_2\text{D}_3$ , DU-145 cells were essentially resistant [81]. This initial and powerful study therefore established the questions of the field, namely: What was the molecular mechanism(s) that mediated sensitivity? What mechanism(s) led to  $1,25(\text{OH})_2\text{D}_3$  resistance?

### 3.1.1 *In vitro analyses of mechanisms that mediate $1,25(\text{OH})_2\text{D}_3$ sensitivity*

Reflecting the analyses of  $1,25(\text{OH})_2\text{D}_3$  actions in leukemia cells, many investigators examined how the cell cycle was  $1,25(\text{OH})_2\text{D}_3$ -regulated in prostate cells. These studies identified VDR regulation of genes that control cell cycle progression, including the cyclin-dependent kinase inhibitors, p21<sup>(waf1/cip1)</sup> and p27<sup>(kip1)</sup> [82], as well as the direct VDR-binding sites on the gene *CDKN1A* (encodes p21<sup>(waf1/cip1)</sup>) [83]. The  $1,25(\text{OH})_2\text{D}_3$  regulation of p27<sup>(kip1)</sup> appears to be mechanistically enigmatic and includes nondirect mechanisms [84,85]. Other genes identified to be direct VDR targets regulated by  $1,25(\text{OH})_2\text{D}_3$  and regulate cell cycle include GADD45 $\gamma$  [86] and IGFBP3 [87].

Again, perhaps less clear in terms of mechanism, but nonetheless biologically impactful, is also the  $1,25(\text{OH})_2\text{D}_3$ -mediated downregulation of MYC mRNA and protein [88]. This is accompanied by dephosphorylation of retinoblastoma protein allowing E2F family members to bind and downregulate cyclin A, ultimately sustaining G<sub>1</sub> cell cycle arrest [85]. Thus, the regulation of cell cycle progression appears to be a clear mechanism by which  $1,25(\text{OH})_2\text{D}_3$  signaling can reduce cell proliferation.

Across cell biology systems, a common theme is that cell cycle arrest is permissive of cell differentiation. For example, treatment of leukemia cells with retinoids, or  $1,25(\text{OH})_2\text{D}_3$ , clearly induces defined differentiation programs that are phenotypically distinct. This is far less clear with PCa cells, or even nonmalignant prostate cells. Various groups have suggested that  $1,25(\text{OH})_2\text{D}_3$ -induced expression of E-cadherin and PSA are concomitant with a more differentiated and adherent luminal cell phenotype [81,82,89], and similarly, there is evidence that  $1,25(\text{OH})_2\text{D}_3$  regulates prostate differentiation factor (PLAB), which is a member of the bone morphogenetic protein family required for growth and differentiation of both embryonic and adult tissues [87]. Direct regulation of individual differentiation genes by  $1,25(\text{OH})_2\text{D}_3$  has been shown in several models. McCray et al. showed accelerated differentiation by  $1,25(\text{OH})_2\text{D}_3$  in patient-derived benign prostate organoids from 11 patients and regulated the WNT pathway via suppression DKK3 [90].

One plausible mechanism by which the VDR may induce prostate differentiation is through cooperation with androgen activity through the androgen receptor

(AR). Certainly, AR is associated with potential prostate epithelial differentiation in a number of ways. First, temporal expression of AR and androgen cross-talk between epithelium and stroma is essential for normal prostate development [91], underscoring paracrine signaling and cross-talk during this process. Secondly, within the epithelium, from which PCa arises, only the secretory, luminal cell populations express AR. Thus, it may be that the VDR augments these actions, perhaps through shared target genes. More specifically,  $1,25(\text{OH})_2\text{D}_3$  induced AR expression in LNCaP, CWR22R, MDA-PCa-2a, and MDA-PCa-2b cell lines [92–96], and for example, LNCaP cells respond differently to  $1,25(\text{OH})_2\text{D}_3$ , depending on the presence of androgens, further suggesting interplay between these two hormones [80]. In the opposite direction, pharmacological inhibition of AR activity abrogated antiproliferative effects of  $1,25(\text{OH})_2\text{D}_3$  in LNCaP cells [95,97]. Although these studies in PCa cell lines support cross-talk between the hormones, functional differentiation was not demonstrated. Furthermore, androgens upregulate VDR expression [98], further supporting the communication between these two hormonal axes. Finally, in PCa patients, several studies have shown that vitamin D supplementation reduced PSA levels [99–101]. Together, this suggests there is a functional cross-talk between the AR and the VDR, which may coordinate cell fate decisions including differentiation.

Despite these mechanisms of potential cross-talk, and hints that the genes coregulated may impact cell lineage, it is unclear whether the actions of the VDR, including with the AR, are sufficient to drive functional luminal differentiation. For example, microarray or RNA-Seq analyses in prostate systems have not clearly established a significant change in luminal gene expression programs that are overtly implicated in differentiation. That is,  $1,25(\text{OH})_2\text{D}_3$  signaling drives a cell cycle arrest, but probably other signals may be required to induce differentiation [102–104] including regulation of WNT signaling [90].

More broadly, other aspects of  $1,25(\text{OH})_2\text{D}_3$  anticancer actions include the suppression of inflammation, inhibition of angiogenesis, reduction in invasion and metastasis, and induction of programmed cell death events in a variety of benign prostate epithelial and PCa cell lines [105–108].

### 3.1.2 *In vivo analyses of $1,25(\text{OH})_2\text{D}_3$ actions*

Given these significant insights into the potential anticancer actions of the VDR in PCa, there has been enthusiasm to exploit murine models to define either chemoprevention or chemotherapy strategies. However, a difficulty in undertaking in vivo studies is, of course, that there are species differences between mice and humans, and consequently the findings may need to

be interpreted cautiously. For example, these differences include that the longevity and the age-associated cancers of mice do not obviously reflect humans, and indeed, there are other key metabolic differences between the two species that may impact on how  $1,25(\text{OH})_2\text{D}_3$  impacts xenograft PCa cells, or genetically engineered mouse models (GEMM) of PCa [109,110]. The murine and human prostates are anatomically distinct, and therefore, how  $1,25(\text{OH})_2\text{D}_3$  impacts these tissues is unclear. Finally, the regime of testing is challenging to recapitulate human PCa, especially in the case of identifying which chemoprevention time windows are most effective. Finally, a crucial challenge for in vivo studies is the dose-limiting hypercalcemic toxicity of treating with  $1,25(\text{OH})_2\text{D}_3$ , and thus, noncalcemic analogs have also been developed with the goal to avoid this deleterious side effect [111,112].

Use of  $1,25(\text{OH})_2\text{D}_3$  and analogs to prevent and/or treat cancer of GEMM mouse models of PCa has in some ways recapitulated the findings in human PCa cell lines, but also yielded mixed results. Treatment of *Nkx3.1;Pten* mutant mice, a transgenic model for PCa, with  $1,25(\text{OH})_2\text{D}_3$  delayed the formation of HGPIN lesions [113]. However, there was no benefit to treating mice with  $1,25(\text{OH})_2\text{D}_3$  after precancerous lesions had formed. In a similar model of *Pten* mutation driving HGPIN, a recent study that used single-cell RNA sequencing (scRNA-Seq) revealed that although a potent noncalcemic analog of  $1,25(\text{OH})_2\text{D}_3$ , Gemeni-72, initially caused apoptosis of most of the HGPIN cells, the surviving ones became more aggressive and displayed upregulated survival pathways [114]. Similar results were observed in the TRAMP mouse, in which  $1,25(\text{OH})_2\text{D}_3$  initially inhibited growth of PCa, but the cells that escaped restraint appeared to be more aggressive and in fact the treated animals displayed an increase in metastatic cancer [115]. It is unclear if this finding recapitulates human PCa although the TRAMP model displays frequent disruption to p53 and Rb [116], which are also highly frequent events in human PCa [117].

Finally, it is interesting to note where the *Vdr*<sup>-/-</sup> mice have been informative in the cancer context. Specifically, crossing the *Vdr*-ablated background into models of tumor disposition phenotypes can reveal biological antagonism between *Vdr* and carcinogenic signals. For example, *Vdr*-deficient and heterozygote background mice exacerbated the aggressiveness of murine breast [118,119] and colon [120,121], but similar experiments have not been reported with well-established murine PCa models, although absence of proof is not proof of absence. However, deletion of *Vdr* in the TgAPT(121) mice (a model of prostate intraepithelial neoplasia) did result in a more aggressive cell state with less programmed cell death [122].

### 3.1.3 Mechanisms of resistance toward the anticancer actions of $1,25(\text{OH})_2\text{D}_3$

A significant focus from multiple investigators has been to identify the resistance mechanisms that suppress the cell responsiveness toward  $1,25(\text{OH})_2\text{D}_3$  and may therefore provide a rationale target for therapeutic cotargeting. A classical approach has been to consider the local autocrine signaling of VDR in the prostate.

In the prostate, there is evidence of extrarenal expression of *CYP27B1* enzyme indicating that local intraprostatic production of active  $1,25(\text{OH})_2\text{D}_3$  may regulate tissue levels of the active hormone [123–125]. PCa cells have decreased *CYP27B1*, thus likely reducing ability to form  $1,25(\text{OH})_2\text{D}_3$  [126,127]. Interestingly, studies have reported vitamin  $\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$  are equally potent in vivo in terms of anticancer actions, supporting a route for local tissue activation [128]; however, reduced expression of *CYP27B1* is observed in PCa cell lines [127]. By contrast, *CYP24A1* is expressed in a frequently amplified region of Chr 20q13 and has putative oncogenic functions [129], and its expression is increased in PCa associated with loss of sensitivity toward  $1,25(\text{OH})_2\text{D}_3$  [130]. Of course, within a tumor microenvironment, the cross-talk with stroma cells can also impact these mechanisms, and there is evidence that VDR signaling in different cell populations needs to be considered [131].

A perhaps more widespread mechanism of disruption of VDR signaling in PCa is through epigenetic mechanisms and has been a subject of significant focus to understand they may disrupt VDR signaling in terms of the ability of the VDR transcriptional complex to function. The rationale for considering that the VDR transcriptional functions are distorted is apparent from considering cells such as DU-145, which are essentially resistant to the anticancer actions of  $1,25(\text{OH})_2\text{D}_3$  [81], but still respond transcriptionally, albeit in a selectively distorted manner, such that classical antiproliferative target genes such as *CDKN1A* are not regulated, whereas the upregulation of the catabolic *CYP24A1* gene is retained [132–134]. These findings demonstrate that a lack of functional VDR alone, or ability to initiate catabolism alone cannot explain resistance, and also support the concept that the VDR transcriptome is altered in cancer cells to disfavor antiproliferative target genes.

One approach has been to examine how CpG methylation patterns impact VDR signaling. In other cancer settings, DNA methylation has been associated with the disruption of expression of the VDR itself [135], and within PCa, altered expression of the *CYP24A1* gene appears to be driven also by changes in DNA methylation [136,137]. Furthermore, the VDR can downregulate DNMTs, leading to gene-specific hypomethylation and resistance to  $1,25(\text{OH})_2\text{D}_3$  [138].

Other studies have pursued how the interactions of VDR with transcriptional corepressors such as NCOR1, NCOR2/SMRT, and LSD1 may be distorted in PCa have been examined to investigate this possibility [133,134,139–143] and also that cross-talk with AR, and its coregulators may also distort VDR functions [144]. In turn, it has been suggested that this enhanced interaction with corepressors presents a therapeutic vulnerability that can be exploited by treating cells with 1,25(OH)<sub>2</sub>D<sub>3</sub> plus HDAC inhibitors [133,134,139, 145,146].

## 4. High-dimensional data approaches to understanding VDR functions in the prostate

### 4.1 Transcriptomic approaches

Gene microarray and subsequently RNA-Seq approaches are the earliest and most widespread high-dimensional approaches applied to prostate systems. Some genes and networks are consistently identified across experiments, but there is much diversity, reflecting different cells examined, time and dose of treatment, and different microarray platforms used with differing numbers of genes, as well as distinct downstream analytical approaches.

In 2003, one of the first microarray analyses in PCa cells (LNCaP) confirmed the *CYP24A1* was a regulated gene target, as was *IGFBP3* but also identified changes in expression of *MAPK* as well as genes such as thioredoxin reductase 1, involved in redox balance, and a number of metallothioneins that are involved in the inhibition of programmed cell death [147]. In the same year, others identified enrichment of genes that were directly regulated by 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR including metabolic enzymes and others involved in the control of fatty acid biosynthesis [148]. Interestingly, in the latter case, this involved genes being directly transrepressed by the VDR, which remains mechanistically enigmatic.

Following on from these initial studies, others [133] examined the context of 1,25(OH)<sub>2</sub>D<sub>3</sub> resistance and the use to HDAC inhibitors to identify regulation of genes that could be restored in PC-3 that were essentially recalcitrant to the actions of 1,25(OH)<sub>2</sub>D<sub>3</sub> alone. This approach also identified signal transduction genes such as *MAPKAPK2* and *GADD45α* reflecting the findings of others, but also identified novel genes including DNA-binding protein inhibitor *ID-1*, which can inhibit a wide variety of basic helix loop helix transcription factors, and perhaps helps to explain the pleiotropic actions of 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR signaling. Extending the concept that 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR may regulate transcriptional mechanisms further was the identification in ALVA-31 cells that the genes regulated at mRNA and protein level

included estrogen receptor alpha, and heat shock proteins suggesting that VDR activation will directly impact how estrogen and androgen will signal in the system, and supporting a cross-talk between these different classes of nuclear receptors [149]. Indeed, this concept has been followed up by a number of investigators, for example, who reported microarray-identified regulation by 1,25(OH)<sub>2</sub>D<sub>3</sub> of AR target genes such as *TMPRSS2* and downregulation of *MYC*; given that *MYC* is a basic helix loop helix transcription factor, it is interesting to speculate that this may reflect the impact of upregulated *ID-1* [150].

The concept of 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR and DHT/AR cross-talk was previously introduced. This cross-talk was further explored by Tenniswood and coworkers who examined the cellular and transcriptional impact of the cotreatment in LNCaP cells [151]. These workers demonstrated cooperative actions on cell proliferation as well as a unique gene set of ~250 genes in the dual treatment. Gene set enrichment identified in upregulated gene ontologies enriched for ion transport, for example, and in the downregulated gene ontologies that included DNA repair. Validation studies confirmed the combinatorial impact on a number of genes including cell cycle genes such as *GADD45G* and *CDC20* as well as others in lipid metabolism such as *HPGD*. These workers also undertook the interesting step of undertaking miRNA microarrays to identify miRNA in inverse correlation with mRNA that could explain the regulation of the observed mRNA. For example, 1,25(OH)<sub>2</sub>D<sub>3</sub>/VDR and DHT/AR downregulated miR-17, which was inversely correlated with the upregulation of a number of genes that block apoptosis. The cross-talk of VDR regulated miRNA and mRNA in incoherent feed-forward loops has been established at the candidate level in nonmalignant prostate epithelial cells [83]. Finally, the regulation of miRNA by the VDR has been examined further, for example, to consider how VDR-regulated miRNA in stromal cells impacts the tumor [152], and identified direct roles for VDR regulation of DICER to explain in part the regulation of miRNA. Others have reported significant diversity in 1,25(OH)<sub>2</sub>D<sub>3</sub> regulation of miRNA across prostate cells [153]. Indeed, the significance of the differences in expression of miRNA in different cells supports a role for secreted miRNA to be prognostic of aggressive PCa, which has been validated by various workers [154].

### 4.2 Cistromic approaches

With the development of chromatin immunoprecipitation coupled with NGS (ChIP-Seq), it has been possible to map the genomic locations of the VDR in a

variety of cell systems [155–159]. To date, there are only three published datasets of VDR ChIP-Seq in prostate cells ([160,161], doi: <https://doi.org/10.1101/2022.01.31.478573>), and one publicly available dataset in LNCaP (GSE64657), but which has not yet been analyzed and published.

Potentially, VDR ChIP-seq studies carry more biological importance than transcriptomic approaches as they establish direct VDR genomic interactions, compared with the combination of direct and indirect actions that are represented by transcriptomic approaches. By contrast, annotation of ChIP-Seq data remains a more complex bioinformatic procedure than transcriptomic approaches as the challenge of establishing meaningful *cis-trans* relationships is a significant one [162,163]. A given cistrome needs to be defined in genomic space, for example, with ChromHMM algorithm [164] to define underlying epigenetic states, or GIGGLE to define overlapped with other cistrome data [165], or the ROSE algorithm to define superenhancers [166,167]. Next, these parsimonious cistrome definitions of the unique and overlapping genomic distributions in different epigenetic states (e.g., in active enhancers, at poised enhancers) in cells/treatments need to be integrated with matched RNA-Seq undertaken in parallel treatments to define cistrome–transcriptome relationships and test their phenotypic associations, for example, using Kolmogorov–Smirnov tests to examine differences in cumulative distribution plots for cistrome-binding sites with respect to nearest gene, using bootstrapping approaches to measure how the specific cistrome relationships associate with gene expression patterns [153]. Needless to say, this can result in considerable variation in the findings generated.

Work by Fleet et al. [160] identified VDR binding at ~3400 protein-coding genes, ~680 long noncoding RNAs, and ~470 miRNAs, which included VDR-bound peaks at known VDR target genes including *CYP24A1* and *IGFBP3*. Interestingly, peak distribution was evenly divided between intergenic and intronic regions, supporting both long-range and proximal regulation. These studies also suggested that  $1,25(\text{OH})_2\text{D}_3$  amplifies signals mediated through other TFs including NF-kappa-B inhibitor alpha (NFKBIA) and FOXO1, and some peaks near immune response-related genes (e.g., *L1R2*) hint toward VDR regulation of immune processes.

These data were also reflected in a VDR-ChIP Seq study in nonmalignant PrE cells [161], which identified VDR-binding sites, again including in well-known targets (e.g., *CYP24A1*) and, interestingly, ligand activation led to a significant decrease in the number of VDR-ChIP peaks, reflecting perhaps an active role for the basal VDR in gene expression. Also of interest in this study was the identification of significant sites where there

was a loss of VDR binding, for example, at the aminoacyl tRNA synthetase genes, which led to decreased proliferation. Interestingly, VDR was also identified to bind near genes regulating neural differentiation, which raises an interesting possibility that VDR genomic functions may be linked to neuroendocrine transdifferentiation in PCa, which occurs in advanced ADT-resistant PCa.

Finally, a recent study [168] addressed VDR function in the context of PCa health disparities by examining a panel of EA cells (HPr1-AR and LNCaP) and AA cell lines (RC43N, RC43T, RC77N, and RC77T). These analyses revealed that the VDR genomic interactions were significantly more frequent and stronger in transcriptional regulator in AA than EA prostate cells and that in PCa this signaling is distorted and suppressed. In nonmalignant RC43N cells, VDR ChIP-Seq identified significant basal and  $1,25(\text{OH})_2\text{D}_3$ -dependent VDR-binding sites, with ~1300 in total associated with transcriptional responses enriched for circadian rhythm and inflammation networks. In parallel,  $1,25(\text{OH})_2\text{D}_3$ -dependent ATAC-Seq also revealed the greatest impact on chromatin accessibility in RC43N cells, with a significant gain of nucleosome-free regions at enhancers. By contrast, in EA and AA PCa cell models,  $1,25(\text{OH})_2\text{D}_3$  led to a loss of VDR binding. Coupled with these different cistromic patterns, proteomic analyses also suggested that genomic ancestry significantly impacted the protein partners within the VDR complex.

Other studies either outside of prostate biology, or within the prostate but not directly examining the VDR, have revealed two other aspects of how the VDR may impact the prostate. Firstly, an obvious concept is how genetic variation impacts VDR function. An initial focus on understanding how VDR function in cancer could be disrupted was to consider candidate SNPs in the receptor itself, which could be characterized by restriction enzyme digestion. This led to the possibility that specific VDR-associated SNPs may be associated with altered VDR function [169]. These findings were initially suggestive of a functional relationship between VDR genetic variation and cancer risk. However, none of these associations are genome-wide significant, and indeed, there are no SNPs in the National Human Genome Research Institute genome-wide association studies (GWAS) catalog that annotates VDR to prostate phenotypes.

An alternative impact of genetic variation is on the sites of VDR binding. Given that more than 90% of human genetic variation is in noncoding regions of the genome, it is not unsurprising that VDR-binding sites may overlap with GWAS SNPs. This is a challenging computational analysis, and several approaches have been developed [170]. Within the context of VDR, VDR cistrome data have been overlapped with GWAS SNPs,

and SNPs in linkage disequilibrium, to test the interaction between disease- and phenotype-associated SNPs at sites of VDR genomic binding. These analyses identified where GWAS SNPs were significantly enriched in VDR cistromes, and for example, identified a significant overlap between VDR and nuclear factor- $\kappa$ B binding sites that contained GWAS SNPs related to immunophenotypes [171]. Given that the number of prostate-specific VDR cistromes is increasing as are the number of studies with GWAS SNPs associated with PCa [10,172–178], revisiting this approach will potentially reveal how germline genetic variation, including as a result of different genomic ancestry, impacts the ability of the VDR to bind and regulate target genes.

Secondly, genomic approaches are beginning to annotate VDR cistromes to address the question of what transcription factors or coregulators are shared at the sites VDR binding. Initial candidate studies of VDR binding suggested that there the specificity of binding for different nuclear receptors was dictated by the nucleotide spacing between hexameric motifs [179]. This very elegant idea has largely been unsubstantiated by cistromic data, and there appears to be a genuine knowledge gap in determining how the specificity of nuclear receptor binding arises. Most likely insights from the 3D genome [180], phase condensates [181–183], and protein–protein interactions will yield significant insights. Indeed, a recent analyses of how VDR functions to form topologically associated domains suggest that the VDR plays a significant role in this capacity [180] and will most likely be highly impactful in considering the function of this receptor in cancer.

Finally, it is also perhaps not surprising that the VDR, as a type II nuclear receptor and being nuclear resident independent of ligand, impacts transcriptional process through a range of mechanisms and indeed recently a so-called bookmarking functions for the VDR have been identified [184]. Within this context of VDR protein–protein interactions, it is interesting to note the corepressor NCOR2 significantly overlaps with VDR motif and cistrome in ADT-resistant PCa cell models, suggesting the VDR functions are suppressed with PCa progression [185] and may include the ability of the VDR to bookmark for other nuclear receptors.

## 5. Lessons from PCa clinical trials with vitamin D compounds

The epidemiological relationships between vitamin D metabolites and risk of aggressive PCa combined with anticancer effects of  $1,25(\text{OH})_2\text{D}_3$  in preclinical models paved the way for clinical trials. Indeed, there has been an active portfolio of clinical trials in the arena of

vitamin D supplementation or treatment with  $1,25(\text{OH})_2\text{D}_3$  PCa for many years considering different aspects of chemoprevention and chemotherapy.

### 5.1 Chemoprevention of PCa by vitamin D supplementation

Epidemiologic studies have shown positive, negative, U-shaped, and null associations between PCa risk and vitamin D metabolites, as detailed before. In an effort, in part, to address these ambiguities, several large-scale randomized supplementation trials are ongoing including the VITAL (VITamin D and omega-3 TriaL), which has accrued  $\sim 25,000$  people and is examining the impact of supplementing vitamin D and omega 3 fatty acid on a range of pathologies, cancer, and heart disease incidence [186]. This 5-year study was randomized, double-blind, placebo-controlled  $2 \times 2$  trial with 2000 IU/d of cholecalciferol, and 1 g/d of marine omega-3 fatty acids in 25,871 men over 50 and women over 55 years of age. There principal results were reported in 2020 for the primary endpoints of cardiovascular disease and cancer risk [187]. The overall incidence of PCa during the trial was 192, with an HR of 0.88 (0.72–1.07) for combined intervention and 1.09 (0.73–1.62) for the vitamin D intervention arm, both of which were not different from placebo. The HR for confirmed metastatic PCa or PCa-specific mortality was 0.43 (0.17–1.12) although also not significant with only 20 total events. When examined by race, AA men had lower HRs for PCa in vitamin D intervention arm, although not significant due to a very low number of events [188].

Although, at first glance, the VITAL results appear to show no benefit to vitamin D supplementation and PCa risk, it is important to consider several factors that impact the results. The first is that there were very few cases of metastatic PCa in the cohort overall, with only 20. It would be nearly impossible to see a benefit with these small numbers, but the results strongly trend in a direction that vitamin D is protective. Secondly, the intervention time of 5 years is very short in relation to a lifetime of vitamin D deficiency. The molecular events leading to carcinogenesis accumulate over a lifetime, and mutations are irreversible. One would only expect a benefit from a short intervention if vitamin D was able to impact the PCa lesions themselves and alter progression. In general, RCTs are designed to test therapeutics with S-shaped efficacy curves and therefore frequently fail for supplementation studies [189]. Another limitation is that we do not know the threshold of  $25(\text{OH})\text{D}_3$  levels needed for nonskeletal effects, which may result in insufficient dosing in RCTs. There are also polymorphisms in vitamin D–related genes that likely

contribute to heterogeneity of response and overall serum 25(OH)D<sub>3</sub> levels.

However, there are clues in this study that the associations between UVB radiation vitamin D<sub>3</sub> and PCa are more striking in AA men. Given that UVB radiation also degrades folic acid, a strong inverse correlation between skin pigmentation and latitude has arisen during ancestral adaptation [190,191]. Relatively, recent rapid dispersion and lifestyle changes have resulted in many individuals currently living in UVB environments that differ profoundly from their ancestral ones. Reflecting this, significant associations have arisen between low serum vitamin D<sub>3</sub> levels and cancer incidence and progression risks among AA PCa patients [51,53,59,192–203]. Furthermore, although vitamin D<sub>3</sub> supplementation in the VITAL cohort [204,205] had no overall impact on cancer incidence, the AA participants experienced a suggestive 23% ( $P = .07$ ) reduction in cancer risk, indicating that larger cohorts may be more informative [188,206,207].

Therefore, a second strategy has been to undertake randomized controlled trials (RCTs) in men with or without PCa using vitamin D supplementation. There are also studies that supplement PCa patients before radical prostatectomy, which have identified and validated molecular targets and pathways regulated by vitamin D metabolites. Cholecalciferol supplementation of men with PCa has shown changes in clinical aspects of the disease as well as molecular targets. In patients with recurrent PCa, cholecalciferol (2000 IU/day) significantly reduces PSA doubling time in a small pilot of 15 PC patients [101]. In a cohort of 44 men with low-risk PCa, 1 year of 4000 IU/d reduced the number of biopsies positive for PCa [208]. Wagner et al. conducted a double-blind, presurgical intervention in PCa patients who were treated with 400, 10,000, or 40,000 IU/d for 8–12 weeks. They observed no toxicity, and the prostate calcitriol levels negatively correlated with the number of dividing cells by Ki67 positivity [100]. The highest dose group also had lower PSA compared with the other dose groups. Using that same cohort, Giangreco et al. showed that the expression of inflammatory genes [124] and microRNAs [209] correlated with prostate 1,25(OH)<sub>2</sub>D<sub>3</sub>. Collectively, these studies demonstrate that prostate tissue is responsive to cholecalciferol supplementation and suggest suppression of inflammatory androgen pathways by cholecalciferol. However, none of these studies included a diverse population of patients.

To identify mechanisms of 1,25(OH)<sub>2</sub>D<sub>3</sub> sensitivity in PCa patients, a number of investigators have considered the option of treating men with localized disease before surgery and then examining the tumor material retrieved after surgery for analyses of VDR signaling pathways. For example, in a pilot study of 40 patients

with localized PCa, Beer and colleagues tested 1,25(OH)<sub>2</sub>D<sub>3</sub> or placebo for 4 weeks before radical prostatectomy [210]. Immunohistochemistry of VDR and known candidate VDR target genes coupled with markers of cell proliferation were examined confirmed 1,25(OH)<sub>2</sub>D<sub>3</sub> responses in the prostate tissue. These and other studies suggest that 1,25(OH)<sub>2</sub>D<sub>3</sub> could be given to PCa patients, even at quite high doses [211], and biological effects could be observed. Indeed, this led to the concept of combining 1,25(OH)<sub>2</sub>D<sub>3</sub>, or more stable formulations, with existing chemotherapies.

## 5.2 Chemotherapy of PCa with 1,25(OH)<sub>2</sub>D<sub>3</sub> and analogs and the impact of genomic ancestry

One such approach was undertaken by Novoclea who undertook a series of clinical trials with a 1,25(OH)<sub>2</sub>D<sub>3</sub> compound, DN-101, in combination with docetaxel in men with advanced prostate cancer who had experienced ADT treatment failure in a randomized phase III study (ASCENT I [AIPC Study of Calcitriol ENhancing Taxotere]) to determine whether the prostate-specific antigen response rate (defined as a >50% decline in prostate-specific antigen for >1 month) was different for the standard therapy for ADT-resistant PCa (docetaxel 36 mg/m<sup>2</sup> weekly intravenously for 4 weeks every 6 weeks) compared with the same dose and schedule of docetaxel plus DN-101, 45 mg weekly. Although this study did not meet the prostate-specific antigen response criteria, it did alter the overall survival and therefore justified a large randomized trial to assess survival. This trial (ASCENT II) was halted before full recruitment because survival in the DN-101 arm was reduced compared with standard of care [212]. In post-trial analyses, there were modifications to docetaxel regime between ASCENT I and II that could have impacted efficacy, and there is a reasonable argument that this clinical failure has impeded subsequent development of vitamin D-centered therapies for illegitimate reasons [213].

Set against these design challenges, and perhaps nuanced biological responses, it is worth reiterating that the links between VDR signaling and anticancer and antiinflammatory actions appear strongest in AA PCa patients compared with EA counterparts [198]. For example, vitamin D<sub>3</sub> supplementation prior to radical prostatectomy significantly altered tumor expression of genes associated with inflammation in AA compared with EA patients [214]. More recently, independently of genomic ancestry, VDR signaling has been associated with regulation of the circadian rhythm [215], reflecting a wider function for nuclear receptors to regulate this key process (reviewed in Ref. [216]).

Together, these data suggest that AA men, compared with EA counterparts, are more acutely sensitive to low serum vitamin D<sub>3</sub> levels that lead to inadequate VDR signaling; this has potentially been overlooked in the clinical evaluation of vitamin D<sub>3</sub> analogs in PCa cohorts that largely consisted of EA men [211,213].

While the mechanistic association between circadian rhythm and innate immunity in patients with high genomic African Ancestry has not been completely studied, circadian rhythmicity is indeed a central feature of both innate and adaptive immunity [217]. Specifically, circadian rhythmicity has been studied in monocytes and macrophages, which are a critical immune cell type within the innate immune system. This can be extremely influential in AA men with PCa that have persistent inflammation and an immunosuppressive tumor microenvironment. For example, a cohort of 3000 Ghanaian, AA, and EA men with PCa men has been used recently to reveal that African genomic ancestry significantly drives a unique systemic immune-oncological signature [218]. Importantly, the suppression of tumor immunity protein signature associates with metastatic and lethal PCa.

Given that multiple clinical studies have confirmed that the VDR plays a crucial role in modulating innate immune responses toward various pathogens [219–223], similarly epidemiological studies suggest an inverse association between circulating levels of 25(OH)D<sub>3</sub> and inflammatory markers, including CRP and interleukin (IL)-6 [224,225], and elevated IL6 in Ghanaian and AA men, which is well documented, is secreted by disease-associated macrophages [218,226,227].

1,25(OH)<sub>2</sub>D<sub>3</sub> or its analogs have been shown to initiate the differentiation of myeloid progenitors into macrophages, and to reduce MCP-1 and IL-6 expression in macrophages [228] as well as interferon (IFN)- $\gamma$  activation within macrophages [229,230]. Indeed, VDR/RXR activation is enriched in tumor-associated macrophages (TAMs) compared to macrophages from normal tissues [231]. Since higher BMI has been associated as a contributing factor to aggressive PCa in AA men [232], Masseti et al. (2022) observed that macrophages isolated from murine prostate tumors that are PTEN<sup>PC</sup> -/-; SMAD<sup>PC</sup> -/- knockout and treated with high-fat diet compared with a low-fat diet demonstrated increased VDR/RXR activation and tumor cell growth [231]. In further support of ancestral for macrophage activation, health donor macrophages isolated from subjects of African ancestry compared with European ancestry demonstrate a differential response when challenged to bacterial. The authors concluded these findings are ancestry related; as macrophages are one of the most conserved cell populations throughout evolution [233]. This is relevant to patients with 25(OH)D<sub>3</sub> deficiency

as it is required for a defense against the intracellular pathogen *Mycobacterium tuberculosis* [222]. Thus, 25(OH)D<sub>3</sub> deficiency in populations with African ancestry could be responsible for these observations as the signaling of the VDR is more potent in the normal prostate to control inflammatory signals and is perhaps most critically impacted by elevated BMI.

Thus, there appears to be a dual effect of 25(OH)D<sub>3</sub>/VDR to direct activity on the cancers from men of African ancestry. Indeed, in the AA derived RC-43T PCa cell lines express higher levels chemokines as well as an overall elevated interferon immune signature compared with LNCaP cells, and this reversed vitamin D treatment [168]. Similarly, Haridman et al. demonstrated that AA prostate cancer patients treated daily for 4 weeks with 4000 IU of 25(OH)D<sub>3</sub> day prior to prostatectomy demonstrated increased inflammatory suppressive immunity compared with EA patients [14]. While the current data available are limited on the direct role of African ancestry on the immune-circadian rhythm signature in macrophages, it is tempting to speculate that paracrine/autocrine signaling between tumor cells recruits and polarizes macrophages toward a suppressive phenotype. This is highly plausible as macrophage inhibitor treatment of the C4B2 xenograft model, which lacks T cells but has an abundance of macrophages, results in decreased tumor growth [234]. Lastly, since similar findings have been observed for VDR activation in dendritic cells, it is imperative that AA PCa patients be oversampled in larger 25(OH)D<sub>3</sub> clinical trials and that VDR activity in both tumor and immune cell populations will be interesting to explore, for example, at the single cell level.

## 6. Conclusion

The connections between the gene regulation functions of the VDR and the biology of the prostate have been the focus of significant study, and it is clear that there are strong relationships in terms of the biological impact on prostate function, and how this signaling appears to be distorted in PCa. The rationale to define these relationships and mechanisms of corruption is that they would offer a route to exploiting this type II nuclear receptor in a chemoprevention or chemotherapy strategy.

Set against this optimism is that several fundamental biological questions remain, and the precise context to target the VDR in PCa remains ill-defined. It remains unclear how separate or integrated are the functions of the VDR in the absence and presence of ligand. What transcriptional pathways are regulated in either context and to what level are these processes integrated? Somewhat implicit in this uncertainty is that the VDR functions do not stand alone, but rather are integrated with

other nuclear receptors and transcription factors. However, it remains to be resolved as to how this cross-talk occurs be it either adjacent but independent genomic binding or shared protein–protein interactions in a genomic context, and to what extent ligand exposure shifts the distribution, and genomic location, between these functions. Presumably, VDR-AR cross-talk in the prostate and PCa reflects this, but to date there is no clear answer about the importance, extent, and biological function of this cross-talk. Given that the VDR is implicated in the interaction with many different transcription factors, these key questions are amplified further.

It is also becoming clear that genomic ancestry is a major determinant of the VDR actions and interactions. That is, the epidemiological and clinical analyses of VDR signaling appear to have the greatest magnitude of biological impact in men of African genomic ancestry. However, this still remains poorly established due to the historical underrepresentation of AA men in PCa prevention or therapy trials. This is a rapidly changing aspect of PCa, and it is likely that more clear answers will emerge. It is possible that within the context of African genomic ancestry that the VDR signaling lies in a more prominent biological fulcrum, combining biopsychosocial process with gene regulatory scenarios required for prostate health, which are a significant target in the etiology of AA PCa.

## 7. Summary points

- Epidemiologic studies show protective of U-shaped associations between 25(OH)D status and risk of aggressive or lethal prostate cancer.
- Men of African Ancestry have a dual disparity in risk of aggressive prostate cancer and 25(OH)D deficiency.
- In vitro and in vivo studies support anticancer effects of 1,25(OH)<sub>2</sub>D<sub>3</sub>.
- Cistromic approaches have identified key targets and pathways regulated by 1,25(OH)<sub>2</sub>D<sub>3</sub>.

### OBJECTIVES

- The following objectives are addressed and placed in the context of current knowledge on the etiology, clinical presentation, and biology of pancreatic cancer.
- To update current evidence on the association between vitamin D and pancreatic cancer risk.
- To provide an updated review of the experimental evidence on the effects of vitamin D on pancreatic cancer cells and the associated tumor microenvironment.
- To update current evidence on the association between vitamin D and prognosis of patients with pancreatic cancer.
- To summarize the results of vitamin D intervention studies in patients with pancreatic cancer.

deaths from PC was almost the same as the number of new cases (466,003 and 495,773, respectively) (<https://gco.iarc.fr/today/home>). Incidence and mortality rates are about 3-4fold higher in high, compared with low/medium, human development index countries and are slightly higher in men than in women [1].

Because of changes in age distribution, population growth, the increased prevalence of risk factors, and improvements in PC diagnosis and registration, the incidence rate of PC has increased worldwide in the past years, and it is expected to increase further in the next two decades. Worrisomely, it is estimated PC will become the second cause of cancer-related deaths in the United States by 2030, unless there is significant medical progress [2].

Pancreatic ductal adenocarcinoma (PDAC) is the most common type of PC (>90%) [3], and the latter term will be used for convenience in this review. PDAC has a dismal prognosis, with a 5-year survival rate of <10% [1] and a 10-year survival rate of 1% [4].

### 1. Pancreatic cancer: an overview

Pancreatic cancer (PC) is the 12th most common malignancy worldwide and the 7th leading cause of cancer mortality. Among gastrointestinal cancers, PC ranks fourth in terms of incidence. In 2020, the number of

#### 1.1 Etiology of pancreatic cancer

From an etiological perspective, PC is a complex disease with several risk factors having been identified, each with relatively modest contributions. Identifying

a Co-first authors.

b Co-senior authors.

the causes of PC is a must to (1) implement primary prevention interventions and (2) define high-risk individuals who are candidates for screening.

The main nongenetic, nonmodifiable, risk factors for PC are older age (most cases occur after the age of 65 years) and ethnicity (in the United States, risk for black populations is  $\geq 1.5$ -fold higher than that for white populations). The leading modifiable risk factor for PC is cigarette smoking. A metaanalysis on the association of smoking with the risk of PC found an odds ratio of  $\sim 1.7$  for current smokers compared with never-smokers [5]; a more recent and comprehensive assessment confirmed this risk magnitude [6]. Smoking cessation reduces risk and, by 14–20 years after cessation, the risk for former smokers drops to that of never-smokers [7,8]. A summary of metaanalyses indicates that the population attributable risk (PAR) for smoking ranges across studies and global regions from 11% to 32% [9]. Heavy alcohol consumers are at 1.6-fold increased risk, compared with abstainers and occasional drinkers [10].

Obese individuals have  $\sim 1.6$ -fold increased risk in comparison with those with normal weight [11]. Type II diabetes (T2D) is also a well-established risk factor. Individuals with T2D have 2.5 times higher PC risk, the risk being higher for new onset T2D (OR  $\sim 6$ ) and insulin users (OR = 3.7) [12]. The relationship between obesity and PC is complex, and results from this study suggest a noncausal relationship between long-standing T2D and obesity and PC risk. On the contrary, PC seems to be causal of new-onset diabetes.

Chronic pancreatitis (CP) is also associated with increased PC risk. For individuals with sporadic CP, the increase in risk may be in the range of 2–5-fold [13,14]. However, the risk is much higher (in the range of 60-fold) for subjects with hereditary CP [15].

Epidemiological studies have also identified a few factors that are associated with a reduced risk of PC. Among them are asthma and allergy, which are associated with a ca. 40% risk reduction [16–18]. Physical activity and dietary intake of fruits and foods containing folate may be associated with a lower PC risk; however, the evidence is unclear [19,20].

ABO blood type has been reported to be associated with PC risk [21,22]. Compared with participants with blood group O, those with A, AB, or B blood groups were at higher risk of developing PC (OR = 1.32, 1.51, and 1.72, respectively) [22].

The oral and gut microbiome have received great attention in the past years. *Porphyromonas gingivalis* has been proposed to be involved in PC development [23,24]. Kartal et al. [25] identified a fecal microbiota signature that can predict PDAC with high sensitivity and specificity. However, whether the association is causal needs to be formally established.

Familial aggregation of PC occurs in approximately 5%–10% of cases [26] as a consequence of inherited genetic changes, shared environmental factors, or the joint actions of both [27]. Family history of PC in first-degree relatives has been consistently associated with increased PC risk [18,28–31]. Results from observational studies suggest that having at least one relative with PC increases the risk of PC between 1.5- and 13-fold [27].

## 1.2 Genetic susceptibility

Germline genetic risk factors may be classified as mutations or common variants on the basis of their frequency: mutations contributing to hereditary syndromes and variants to sporadic cases [26]. Approximately 2% of all cases correspond to hereditary syndromes (hereditary PC, HPC) caused by low-frequency, highly penetrance, germline mutations in *BRCA2* or *BRCA1* (hereditary breast-ovarian syndrome), *p16/CKDN2A* (familial atypical multiple mole melanoma syndrome), *PRSS1*, *PRSS2*, *SPINK1*, or *CTRC* (hereditary chronic pancreatitis), *STK11/LKB1* (Peutz-Jeghers syndrome), *CFTR* (cystic fibrosis), *APC* (familial adenomatous polyposis), *TP53* (Li-Fraumeni syndrome), *MLH1* or *MSH2* (Lynch syndrome), and *ATM* (DNA repair) [18,26,27].

Approximately 90% of PC cases are sporadic. A total of 16 regions harboring common single-nucleotide polymorphisms (SNPs) with modest risk effects have been identified through genome-wide association studies (GWAS) in populations of European ancestry [18,32–36]. A recent PC GWAS complemented with genome spatial autocorrelation analysis and functional in silico analysis of public genomic information and Hi-C interactions identified 51 additional candidate variants in 17 genetic susceptibility regions associated with PC risk [37].

Despite the effort placed in identifying PC risk factors, there is a great need to emphasize prevention. The low prevalence of PC hampers the use of preventative/early diagnosis/screening strategies in the general population, and the identification of subjects with a higher risk of PC remains a major goal. This is the main scenario where a putative role of vitamin D might play a role in the future.

## 1.3 Clinical presentation and treatment

PC is one of the most challenging tumors to treat: most patients present with locally advanced or metastatic disease, and up to 30% of patients have cachexia at the time of diagnosis. Together with the advanced age, these factors impose significant therapeutic limitations. Radical surgery can only be considered in

approximately 20% of patients and should be carried out only in high-volume centers. Several clinical trials have shown the benefit of adjuvant chemotherapy [38–40]. Recent advances in the use of neoadjuvant chemotherapy support its benefit in patients with borderline resectable disease [41,42]. In patients with metastatic disease, the two main therapeutic schemes are FOLFIRINOX (or variants thereof) and gemcitabine/abraxane; the former has superior antitumor effects but also has a greater toxicity and is generally reserved for patients with better performance status. Nevertheless, the overall life expectancy of patients with metastatic PC is 6 months. The role of radiotherapy in the management of PC is controversial, particularly in the perioperative setting. PC has not yet benefitted from the impact of immune therapies in the standard setting. PC patients often need to receive supportive care to mitigate weight loss, including digestive enzyme replacement due to exocrine pancreatic insufficiency. PC is also associated with pain, sometimes excruciating, that requires analgesics, including opioids.

Undoubtedly, improved therapies are necessary to reduce PC-related mortality, but significant progress will require advances in multiple research areas.

## 2. Pancreatic cancer and vitamin D: epidemiological studies

The relationship between sun exposure, vitamin D, and PC risk has been studied in several types of epidemiological studies, including ecological, case–control, and cohort studies. Overall, these studies have provided inconsistent results. The strategy used to review the available information is shown in Fig. 92.1. The main findings are summarized in Tables 92.1–92.3 (Box 92.1).

### 2.1 Solar Ultraviolet-B radiation

Both ecological and observational studies have reported the existence of a gradient, with inverse relations between solar UVB radiation exposure—using metrics such as latitude, solar radiation data, temperature, time spent outdoors, or other UV radiation-related factors—and the incidence and/or mortality rates due to PC.

*Ecological studies* have leveraged on various types of data (e.g., geographical, solar radiation, or temperature) to investigate the association of solar UVB dose or exposure with PC incidence and/or mortality rate using country-specific or multicountry data.

*Geographical* ecological studies, for example, those carried out in Japan [43,44] and Spain [45,91], among others, have consistently found an inverse relationship between latitude and PC incidence/mortality rates.

*Ecological studies* using solar radiation data in specific geographical regions (i.e., countries) have also reported an inverse relationship. Mizoue [47] used annual hours of solar radiation received from 1961 to 1990 as measurement in Japan and observed a moderate, inverse, association with six gastrointestinal cancers, including PC. A similar inverse relationship with PC risk was found by Kinoshita et al. [48] using the average of daily-accumulated solar radiation (1971–2000) as measurement, using data from the Japan Meteorological Agency. They also reported that low temperature might associate with an increased PC risk. In the United States, Grant [49] found an inverse association between measurements of UVB radiation and PC mortality rates. Similar findings were reported by Boscoe and Schymura [50]. Mohr et al. [46] found that, with occasional exceptions, countries from both hemispheres with lower UVB irradiance had higher age-standardized incidence rates of PC for both sexes (International Agency for Research

<sup>a</sup>High dose. Patients will receive a high dose—180,000 I.U. (1 drop equals 400 I.U.) of vitamin D<sub>3</sub> orally on day 1, and then 4000 I.U. for 60 days; Standard dose. Patients will receive a standard dose—800 I.U. (equals two drops) of vitamin D<sub>3</sub> orally for 60 days.

**BOX 92.1****Summary of the main epidemiological findings**

- Epidemiological studies exploring the relationship between vitamin D and PC risk, using various designs and exposure assessment strategies, have provided inconsistent results.
- Mendelian randomization analyses do not support a causal link between vitamin D levels and PC risk.
- Intervention *studies* have not assessed the impact of vitamin D supplementation on the incidence of PC.
- Clinical trials testing the effect of the administration of vitamin D analogs in combination with chemotherapy did not improve overall survival.

on Cancer [IARC] Global Cancer [GLOBOCAN] database [latest year for which complete data were available was 2002]).

In a review of ecological studies from multiple countries, Grant [51] reported a consistent strong inverse correlation between *solar UVB* exposure and risk for 15 types of cancer, including PC. Similar results were obtained by Moukayed and Grant [52] in a later review. Garland et al. [53] analyzed the association of UVB irradiance measured using NASA satellite data, adjusted for cloud cover, and the age-standardized PC incidence rates, obtained from GLOBOCAN in 2008. They found that both male and female residents of countries with low UVB irradiance had approximately sixfold higher PC incidence rates than those of countries with high UVB irradiance, after adjustment for traditional PC risk factors.

Regarding sex, the reports have been discordant. Mizoue [47] found that the inverse correlation was stronger for men ( $\rho = -0.51; -0.53$  vs.  $\rho = -0.32; -0.31$ ), and Boscoe and Schymura [50] showed evidence for a north–south gradient PC incidence/mortality gradient only among females. In a review, Grant [51] reported that the inverse correlation was significant for males ( $\rho = -0.46$ ,  $P$ -value = 0.005) and borderline for females.

Although these ecological studies are useful for hypothesis generation, they have important limitations, including the use of grouped data: the impact of climatic factors on the human body varies depending on individual lifestyles and occupations, UVR exposure may be a proxy or marker of some other cancer risk factor, and it may be difficult to appropriately control for confounders, among others. In the case of PC, a specific confounder that needs to be considered is depression since it may be an early symptom of PC [92], and it is also inversely associated with the intensity of solar radiation [93]. Another possible confounder is the consumption of animal products. For example, Grant et al. [54] used age-adjusted incidence rates for 21 cancers for 157 countries in 2008, considering dietary supply among other

confounding factors, and found that the correlation between PC incidence and latitude decreases when the animal product consumption was considered.

Other epidemiological designs providing a higher level of evidence than ecological studies have been used to assess the association between UVR exposure and PC risk, including observational case–control, cohort studies, and metaanalyses. In a case–control study conducted in Australia, Tran [55] analyzed the association between UVR exposure—using data collected through questionnaires and NASA’s Total Ozone Mapping Spectrometer to estimate *ambient UVR*—and PC risk. They showed that being born in or living in areas with higher ambient UVR was associated with ca. 30%–40% lower risk of PC. Prospective studies have also confirmed this association: Lin [56] examined ambient UVR exposure and PC risk in the National Institutes of Health (NIH)-AARP Diet and Health Study. After adjusting for multiple potential confounders (e.g., gender, age, BMI, diet, smoking, education, and physical activity), they found a nonlinear relationship, suggesting that different biological mechanisms may underlie the association.

## 2.2 Oral intake of vitamin D

Approximately 10% of the endogenous vitamin D comes from the diet—cholecalciferol (vitamin D<sub>3</sub>)—with egg yolk, liver, or oily saltwater fish being the main animal sources. The plant-derived ergocalciferol (vitamin D<sub>2</sub>) is found in mushrooms, among others. Food fortification is an additional dietary source.

The lack of reliable biomarkers of long-term exposure to specific dietary components has led to the use of recall methods, such as quantitative food-frequency questionnaires, to assess the association with many cancers, including PC. The results of such studies have been contradictory, probably due to confounding as well as to the complex association between intake of dietary vitamin D, calcium, or other vitamins (e.g., retinol) and PC

risk. Some studies have found that vitamin D intake is protective [64,67,69], whereas others have not found an association [65,67,69] or have even made opposite observations [66,68,69].

*No significant association.* In a case–control study from Italy, Bravi et al. [65] studied micronutrients and PC risk (vitamin D intake being categorized in quintiles), reporting a nonsignificant positive association. In a pooled analysis of 14 cohort studies from Europe, North America, and Oceania including subjects of a diverse age range (15–107 years), no statistically significant associations were observed between dietary vitamin D during adulthood and PC risk [67]. In a metaanalysis of observational studies comparing high dose versus low dose, no significant difference in PC risk was reported [69].

*Protective factor.* Skinner et al. [64] found, in two large prospective cohort studies (HPFS and NHS), that intake of 300–449 IU vitamin D<sub>3</sub>—ascertained before PC detection using food frequency questionnaires—was associated with a 43% decreased incidence of PC. They also found that, compared with participants consuming <150 IU/d of vitamin D, those who consumed >600 IU/d had 41% lower risk of PC after adjusting for retinol intake. In these studies, they did not find a significant association with either total calcium intake or calcium from food after adjusting for total vitamin D intake. They also investigated the association with the dietary items contributing vitamin D and nonsignificant associations with PC risk were reported. Giovannucci et al. [72] found decreased relative risks for PC, among other cancers, among subjects with a high vitamin D status index, derived from multiple factors including oral intake, among men enrolled in the Health Professionals Follow-Up Study. A recent metaanalysis of three prospective studies [64,70,71] reported a decrease of 25% of PC risk for a vitamin D (10 µg) intake [69].

*Risk factor.* In a population-based case–control study, using a semiquantitative food-frequency questionnaire, Zablotska et al. [66] reported different risk patterns among men and women. In men, an increased PC risk was associated with currently recommended dietary vitamin D intake levels (highest [ $\geq 450$  IU/day] versus lowest [ $< 150$  IU/day] intake, OR = 2.6, trend- $p = .009$ ) and total vitamin D intake from diet and supplements (for  $< 800$  IU/day), even after adjusting for potential confounders such as calcium and retinol intake. However, no associations were found in women.

In a pooled analysis of 2963 PC cases and 8527 controls from the Pancreatic Cancer Case–Control Consortium (PanC4), a modest significant positive association was found between dietary vitamin D intake and PC risk (OR = 1.13 per 100 IU/day; OR  $\geq 230$  vs.  $< 110$  IU/day = 1.31) [68]. This association seemed to be stronger in people with low retinol/vitamin A

intake. The same study investigated the role of supplementary vitamin D intake in relation to PC risk and found no association. However, when the estimates of one of the studies (the Queensland Pancreatic Cancer Study) were excluded, the pooled OR for supplementary intake ( $\geq 400$  IU/day vs. none) increased from 1.03 to 1.20 (95% CI 0.95–1.50,  $P$ -heterogeneity = 0.35) and the pooled OR for total intake became significant (OR = 2.01, 95% CI 1.50–2.69,  $P$ -heterogeneity = 0.66).

The relationship between vitamin D intake and PC risk has been also investigated using the consumption of dairy products as proxy, since they naturally contain calcium and are often fortified with vitamin D. Unlike in other gastrointestinal cancers, no associations of dietary calcium and vitamin D with PC risk were found [94]. In an analysis of 14 cohort studies, no association between PC risk and intake of dairy products—including total milk, whole milk, low fat milk, cheese, cottage cheese, ice cream, or yogurt—was found [67].

One important caveat of the studies described before is that the effects of vitamin D may be counteracted/modified by a wide range of factors, which may explain the inconsistent findings. Zablotska et al. [66] found no evidence of statistically significant interactions between vitamin D intake and retinol in relation to PC risk. These authors found weak evidence that smoking is a modifier of the effect of vitamin D intake on PC risk in women, but not in men. Genkinger et al. [67] found that smoking significantly modified the associations between cheese and total vitamin D and PC risk, so that former smokers who consumed cheese had an increased risk, while this association was not significant in non- or current smokers.

### 2.3 Ethnicity

The differences in PC incidence and mortality according to ethnicity have led to investigate this variable, since vitamin D insufficiency is more common in the black population compared with others [95]. Several studies have found a high prevalence of vitamin D insufficiency in dark-skinned people [72], likely resulting from higher amounts of melanin, which effectively filters UV-B radiation, with possible contributions from other lifestyle differences. In a study of male health professionals, Giovannucci et al. [72] found a higher cancer mortality (and to a lesser extent, in incidence) among blacks than in their white counterparts, despite comparable socioeconomic status, medical knowledge or use of screening tests, or adherence to a healthy lifestyle and dietary habits. In an Australian case–control study, Tran [55] found that people with fair skin had 47% (95% CI 0.37–0.75) lower risk of PC than those with dark skin. However, a causal relationship has not been established.

## 2.4 Genetics

Several epidemiological studies have explored the role of polymorphisms in *VDR* and genes in the vitamin D pathway in relation to the risk of multiple cancers, including PC. However, there is no evidence for a substantial influence of any single common variant on PC risk.

In a population-based case–control study investigating the association between 87 SNPs in 11 vitamin D pathway genes and PC risk, Anderson et al. [75] did not find any significant association. Similar observations were made by Arem et al. [76]. However, in a small case–control study conducted in China, Li et al. [77] found two polymorphisms in *VDR* associated with PC risk (*VDR*-rs2228570-C: direct association; *VDR*-rs1544410-A: inverse association).

Dimitrakopoulou et al. [96] explored a polygenic score for circulating 25-hydroxyvitamin D (25(OH)D, calcidiol) concentrations, using four SNPs (*GC*-rs2282679, *CYP2R1*-rs10741657, *DHCR7*-rs12785878, and *CYP24A1*-rs6013897), and found little evidence of association with the risk of any of seven incident cancers analyzed, including PC.

## 2.5 Serum/plasma levels of vitamin D

Several studies with different epidemiological designs have been conducted to evaluate the association of serum 25(OH)D, reflecting vitamin D status from both sun and diet, with PC risk. However, the results are conflicting.

Ecological studies analyzing the relationship between estimated serum 25(OH)D levels and PC incidence rate have found an inverse dose–response association that follows a sigmoid curve [46]. Three prospective studies obtained information on circulating 25(OH)D levels. In the ATBC cohort of male Finnish smokers, subjects with higher vitamin D levels had nearly threefold increase in PC risk (highest vs. lowest quintile: OR = 2.92, 95%CI: 1.56–5.48, *p*-trend = 0.001) [57]. However, these results may not be generalizable to other populations such as nonsmokers, women, or residents from other geographical areas. These results were not replicated overall in the PLCO study, conducted in the United States: among individuals with low UVB residential exposure, higher 25(OH)D concentrations were positively associated with PC risk [58]. The Vitamin D Pooling Project, including eight cohorts (among them, the ATBC and PLCO) [74], aimed to investigate the relation of 25(OH)D and six rare cancers [59]. They validated the previously reported results for PC, showing an increased risk associated with very high levels ( $\geq 100$  nmol/L; OR<sub>adj</sub> = 2.12, 95% CI: 1.23, 3.64) [71]. This association remained in a sensitivity analysis

upon removing each individual study, and it was independent of sex, ethnicity, obesity, and diabetes mellitus. However, no significant associations were observed for participants with lower vitamin D status, and no reduced risk between prediagnostic status and PC risk was found overall. The results suggested a nonsignificant U-shaped association when cases occurred during the first 5 years of follow-up were excluded. However, Baggerly and Garland [97] pointed out that the U-shaped curve could be a statistical artifact due to the cut-off points chosen to define the groups.

Piper et al. [60], analyzing a higher number of cases from the PLCO study, validated the association between very high levels of serum 25(OH)D and PC risk described before. There was no significant association for individuals with very low levels ( $< 25$  nmol/L). Contrarily, Wolpin et al. [36] found, in five large prospective cohorts, that participants with higher plasma levels of 25(OH)D had lower PC risk (*p*-trend = 0.03). The inverse relationship was also found in the subgroup analyses conducted in white women and men.

Unlike the reports described before, others did not find a significant association. Shang-long et al. [73] performed a metaanalysis of nine studies with data on circulating 25-OH-D levels and found no evidence of association (OR = 1.04; 95% CI 0.93–1.17). Similarly, in a combination of European cohort studies (EPIC and HUNT2) including 738 primary incident PC cases and matched controls, van Duijnhoven et al. [61] found that higher prediagnostic vitamin D concentrations were not associated with PC risk. Recently, in a Mendelian randomization study performed using the resources of UK Biobank, it was evaluated whether genetically predicted 25(OH)D concentrations are associated with overall cancer susceptibility and cancer mortality (including 500 PC cases) using five 25(OH)D genetic markers (*GC*-rs2282679-G, *CYP2R1*-rs10741657-G, *CYP2R1*-rs116970203-A, *DHCR7*-rs12785878-G, and *CYP24A1*-rs6013897-A) [62]. Results ruled out all but very small effects, suggesting that an overall increase in 25(OH)D levels does not reduce the overall cancer risk. As for PC, MR estimates for the association of a 20 nmol/L increase in 25(OH)D concentration were nonsignificant using either the resources of UK Biobank only (OR = 1.09; 0.63–1.88) or in combination with the PanScan study (OR = 1.21; 0.87–1.68). These results do not support the implementation of vitamin D supplements in the general population to reduce PC risk, although individuals with extreme deficiency might benefit.

Other aspects have also been analyzed, and no evidence of significant interactions between the 25(OH)D status and PC risk factors or exposures have been identified, including month at blood draw [36], region of residence [36], age [36], smoking status [36,57,58,61], sex [58,61], physical activity [36,58,61], BMI [36,61], alcohol [61],

diabetes [61], fasting time [36], total vitamin A intake [57,58,61], calcium [61], or multivitamin use [36,61].

Of note, Stolzenberg-Solomon et al. [58] found a significant interaction between annual solar UVB exposure and 25(OH)D status in relation to PC risk: individuals with low estimated annual UVB residential exposure with high 25(OH)D concentrations had a higher PC risk than those with low 25(OH)D concentrations. However, among subjects with moderate to high residential UVB exposure, 25(OH)D concentrations were not associated with PC risk.

### **2.5.1 Vitamin D insufficiency/deficiency in patients with PC**

Vitamin D insufficiency ( $\geq 20$  and  $< 30$  ng/mL serum 25(OH)D) and deficiency ( $< 20$  ng/mL serum 25(OH)D) are common among patients with PC; it is not clear whether this results from insufficient vitamin D intake or insufficient endogenous 25(OH)D synthesis in the liver. The effects derived from pancreatic resection should also be considered.

As part of an intervention study, Klapdor et al. [98] found that 92.4% of 103 PC patients had 25(OH)D levels  $< 30$  ng/mL at the time of patient recruitment. In a retrospective study of 178 PC patients, Cho et al. [78] found that 49% were vitamin D deficient and an additional 25% were vitamin D insufficient. In their series, low vitamin D levels were independent of the season or their BMI. In the context of a randomized clinical trial (CALGB 151006) including 256 patients, Van Loon et al. [81] found that 44.5% and 32.4% of patients were vitamin D deficient or insufficient, respectively. McGovern et al. [83] studied 627 previously untreated PC patients and found that 47.2% and 30.0% were 25(OH)D insufficient or deficient, respectively. Using data from five prospective cohorts, Yuan et al. [79] reported that 33% and 43% of them had deficient or insufficient levels, respectively. A variety of factors may influence the serum levels of vitamin D, including ethnicity, BMI, disease stage, and season of sample collection. Studies have found that the median 25(OH)D level was significantly lower among patients with stage I and II disease and among nonwhite patients [78,81,83], and McGovern et al. [83] found a significant inverse association with BMI, in line with the results reported in healthy individuals. A potential explanation of the lower vitamin D levels found in obese and overweight individuals is that vitamin D accumulates in subcutaneous fat. Longitudinal studies should shed light on this relationship.

### **2.5.2 Predicted levels of plasma 25(OH)D**

Some studies have used predicted levels of plasma 25(OH)D to assess associations, when no direct measurements were available. Obviously, the lack of direct analytical data is a major limitation. Bao et al. [71]

used a score composed of multiple major determinants of vitamin D status (e.g., race, geographic region, vitamin D intake, body mass index (BMI), and leisure time physical activity) to predict long-term plasma 25(OH)D levels [72]. They found that individuals with higher 25(OH)D score were at lower risk of PC. This association held in the analyses stratified by gender. There were no significant interactions with sex, age, follow-up years, region, smoking status, BMI, physical activity, dietary vitamin D intake, retinol, calcium, multivitamin, or supplemental vitamin D use.

### **2.5.3 Circulating vitamin D-binding protein**

The effects of vitamin D are mediated a variety of biological factors in addition to the VDR, including the levels DBP, a member of the albumin, and alpha-fetoprotein gene family that plays a major role in the transport of vitamin D metabolites in blood. Vitamin D is routed to the liver by DBP, where it is converted to 25(OH)D. In a metaanalysis comprising 28 independent studies of a variety of tumors, including PC (two studies [63,75]), Tagliabue et al. [99] found a suggestive inverse link (OR = 0.75; 95% confidence interval [CI], 0.56–1.00) between DBP levels and cancer risk. However, neither Weinstein et al. [63] nor Piper et al. [60] found a significant relationship between DBP levels and PC risk.

Interestingly, the study of Weinstein et al. [63] found a significant interaction between prediagnostic DBP and 25(OH)D levels in relation to PC risk among Finnish men (Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study): the association was inverse in men with high 25(OH)D levels but not in those with low 25(OH)D levels. Moreover, among men with higher 25(OH)D levels, those with low serum DBP showed fivefold elevated risk of PC, while in those with high DBP the association with PC risk was weaker. There were no significant associations between DBP levels and fat intake, vitamin D, calcium, ethanol, smoking, and years between blood collection and study inclusion.

### **2.5.4 Vitamin D status**

A metaanalysis considering vitamin D status and including nine papers (six with data on circulating 25-OH-D levels, two reporting dietary intake of vitamin D, and one examining the effect of previous extensive sun exposure on PC risk) did not find evidence of the association between vitamin D status and PC risk [73].

## **3. The biology and genetics of pancreatic cancer**

### **3.1 The somatic genetics of pancreatic cancer**

Four major genes are altered in PDAC: the oncogene *KRAS* and the tumor suppressor genes (TSG) *CDKN2A*,

*TP53*, and *SMAD4*. Following the approach applied to study colon cancer development/progression and based on the definition of putative preneoplastic lesions found/enriched in the pancreas of patients with PDAC, a progression model has been established [100]. The morphology of PDAC and of the preneoplastic lesions defined as Pancreatic Intraepithelial Neoplasms (PanIN) pointed to a ductal origin, but the cell of origin of human PDAC remains unknown. The accepted progression model suggests that preneoplastic lesions evolve from PanIN-1 (low grade) to PanIN-3 (high grade) stages [101]. Low-grade PanINs are mucinous hyperplastic lesions that can display a flat or papillary morphology, low proliferation, and lack dysplastic features. High-grade PanINs are characterized by less abundant mucus-containing cells, dysplasia, and higher proliferative activity [102]. Other, less frequent, PDAC precursors include intraductal papillary tumors and mucinous cystic tumors. There is essentially no information on the relevance of vitamin D in the latter; therefore, this chapter will focus on the PanIN-PDAC pathway.

The genetic analysis of PDAC was paralleled by the analysis of PanINs, leading to a model that supported that *KRAS* mutations represent the initiating event [103]. Thus, *KRAS* hotspot mutations occur in >90% of PDAC, and they can also be detected in a high fraction of low-grade and high-grade PanINs. Recent evidence suggests that mutant:wild-type allelic imbalances occur during tumor progression [104,105]. The model posits that the inactivation of TSGs drives the evolution toward high-grade PanINs/PDAC. *CDKN2A* is inactivated in almost all PDAC through various mechanisms including point mutations, allelic losses, and epigenetic silencing. *CDKN2A* genetic alterations have been found in PanIN-2—but not in PanIN-1—lesions, and they are thought to precede *TP53* and *SMAD4* alterations. The p53 pathway is inactivated almost universally in PDAC, largely through point mutations but also through allelic losses and MDM2 amplification. *SMAD4* is mainly inactivated through homozygous deletions (in approximately 50% of tumors), but point mutations/deletions occur in an additional 10% of tumors [103]. Genetic alterations in other members of the TGF- $\beta$  receptor signaling pathway also contribute to its inactivation in a subset of PDAC. The frequency of alterations in these genes varies across studies, largely because PDAC is a very desmoplastic neoplasm, and a careful microdissection is required to produce a high-quality map of the genetic makeup of the tumors. Introduction of gain-of-function (*Kras*) and/or loss-of-function mutations (TSGs) in these four genes in pancreatic epithelial cells in mice recapitulates many aspects of PDAC in humans and supports a possible origin of PDAC in acinar cells [106].

Autopsy studies have established that low-grade PanINs are highly prevalent in the pancreas of individuals without known pancreatic diseases and that their frequency increases with age. By contrast, high-grade PanINs are exceedingly rare except in the pancreas of subjects with PDAC [107]. A recent multicenter genetic study of high-grade PanINs from individuals without PDAC suggests that the genetic alterations that characterize these lesions are less well understood: while PanIN-3 from subjects with PDAC generally harbor alterations in the three major TSG involved in this tumor, the lesions from subjects without PDAC display a much lower frequency of alterations [108]. This has led to propose that many of the seemingly PanIN-3 lesions found in the pancreas of patients with PDAC correspond—in fact—to ductal cancerization, a phenomenon through which tumor cells invade the luminal aspect of the ducts [108].

This “uniform” scenario of genetic alterations is paralleled by alterations in a large number of additional genes that are mutated only at low frequency (“private”). Such a genomic landscape was first shown by Jones et al. [109] and then confirmed using massive parallel sequencing by the Australian Pancreatic Cancer Genomics Initiative [110], the Canadian ICGC study [111], and the TCGA [112]. In these studies, most case samples analyzed came from patients with resectable tumors. While we have a less comprehensive understanding of the genomics of metastatic disease, the available evidence supports the notion that metastatic spreading is associated with epigenetic rewiring.

### 3.2 Pancreatic cancer molecular subtypes

Genome-wide transcriptomic analyses have allowed dissecting the heterogeneity of PDAC. Collisson et al. used microarrays to acquire expression data from untreated, resected, PDAC cancer samples and identified three molecular subtypes: classical, quasi-mesenchymal (QM), and exocrine-like [113]. The classical subtype displayed high epithelial and adhesion gene expression profile, high levels of transcription factor GATA6, dependency on *KRAS*, and better outcome after resection. In contrast, the QM subtype showed high expression of mesenchymal genes, low levels of GATA6, and worse outcome. The exocrine-like subtype was enriched in transcripts coding for digestive enzymes and had an intermediate outcome [113]. However, there have been concerns about the true existence of the latter group, which could reflect contamination by normal exocrine tissue.

To overcome the challenge of bulk tumor analysis, Moffitt et al. applied nonnegative matrix factorization (NMF) to perform virtual microdissection of primary

and metastatic PDAC samples. With this approach, two tumor subtypes—classical and basal—and two stromal subtypes—normal and activated—were identified. The classical subtype was overlapped with Collisson's classical subtype, whereas the basal subtype was characterized by the expression of genes found also in breast and bladder basal tumors (e.g., epidermal keratins and laminins), worse outcome, and possibly more benefit from adjuvant chemotherapy [114]. The Australian International Cancer Genome Consortium project extended the analysis using RNA-Seq data from 96 PDAC with a high epithelial content (>40%) and discovered four stable classes of PC—squamous, pancreatic progenitor, immunogenic, and aberrantly differentiated endocrine exocrine (ADEX). These four subtypes were also present in the extended set of 232 PDACs using array-based mRNA expression profiles encompassing the full range of tumor cellularity. The TCGA-PDAC study also provided support to the existence of similar subtypes [112], and together with other studies, it shows a high correlation between the transcriptomic and epigenetic subtypes [115]. The commonalities and differences between these classifiers have been reviewed recently [116]. Using microarrays and formalin-fixed paraffin-embedded tumors, Puleo et al. identified five distinct subtypes according to tumor- and microenvironment-derived signatures. This classifier included samples with low tumor cellularity. Samples with low stromal signals contained pure classical and pure basal-like subtypes. The other three subtypes were defined by the impact of high stromal content, including immune classical, desmoplastic, and stroma-activated subtype [117].

Chan-Seng-Yue et al. used LCM-purified PCs and whole-transcriptome sequencing of 248 patient tumors. In this series, each of the previously defined classical and basal-like subtypes was split into two subtypes (basal A and B and classical A and B), while a hybrid subtype emerged [104]. scRNA-Seq supported (1) the coexistence of cells belonging to multiple subtypes within a given sample and (2) the existence of a continuum of states ranging from “pure classical” to “pure basal” with the ability of cells to switch from one subtype to another [118–120].

Building on this concept, and using independent component analysis, Nicolle et al. have proposed that a continuous—rather than a discrete—strategy be used to classify tumors. Their signature has been validated in fine needle aspiration/biopsies [121]. This is an important contribution given that most patients with PDAC do not undergo surgery.

More recently, the combination of scRNA-Seq and spatial transcriptomics suggests even more complex scenarios with potential clinical relevance. Raghavan et al. have profiled metastatic samples and organoids to confirm the existence of transitional tumor phenotypes

influenced by signals from the tumor microenvironment [122]. In addition, Hwang et al. have proposed the existence of a neural-like progenitor subtype that is enriched in patients undergoing resection after receiving chemoradiotherapy, associated with poor prognosis [123].

In summary, tumor and stromal cell heterogeneity, intrinsic plasticity, selective pressures, and adaptive responses contribute to an increasingly complex scenario underlying PDAC diversity. The clinical usefulness of these analyses remains to be established in well-designed prospective studies, preferably in the context of clinical trials. Even though the molecular taxonomy of PDAC provides a great opportunity to accelerate the development of personalized medicine strategies, the scenario remains challenging.

### 3.3 The tumor microenvironment in pancreatic cancer

Tumor development is a highly interactive process involving not only the prospective neoplastic cells but also many normal host cellular components that promote or suppress clonal evolution required for tumor formation. Nonneoplastic host components continue to play key roles once the tumor is established, contributing to generate “the tumor microenvironment” (TME). In PDAC, the TME is particularly relevant as the stroma may comprise up to 90% of tumor mass [120,124]. The TME includes the extracellular matrix (ECM) and a wide variety of cell populations, such as cancer-associated fibroblast (CAFs), vascular endothelial cells, pericytes, neurons, and infiltrating immune cells.

*Cancer-associated fibroblasts.* Among all stromal cells, CAFs play a particularly important role owing to their capacity to secrete ECM proteins, proangiogenic, and immunomodulatory factors, all of which may contribute to the environment permissive for tumor growth and invasion [125]. The high-level production of collagen by CAFs, and the ability of collagen fibers to increase tissue stiffness and provide mechanical signals, has been proposed to contribute to the early and rapid dissemination of PDAC cells. The major source of CAFs in PDAC are pancreatic-stellate cells (PSCs), which occur in a quiescent state in the healthy pancreas and can also originate from the pancreatic mesothelium [126]. Quiescent PSCs accumulate vitamin A droplets; upon activation, they start to express  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA), desmin, glial fibrillary acidic protein, and acetylcholine receptors [127] and produce high levels of collagen and other ECM components. Moreover, pericytes, monocytes, adipocytes, mesothelial cells, and bone marrow-derived or adipose-derived mesenchymal stem cells can also transdifferentiate into CAFs [128–131].

CAF identification/isolation is limited by the lack of truly specific markers. They are often identified by negative selection of endothelial (CD31), epithelial (EpCAM), and hematopoietic (CD45) lineages. Most CAF markers (PDGFR $\alpha$ , PDGFR $\beta$ , PDPN, THY1, or  $\alpha$ -SMA) are neither unique nor uniformly expressed. In PDAC, Öhlund et al. first showed the existence of spatially restricted and functionally distinct CAF populations:  $\alpha$ -SMA+ myofibroblasts (myCAFs) are closely associated with tumor cells, whereas those that are IL6-expressing (iCAFs) are more distant. By RNA sequencing, they identified unique transcriptional signatures that implied that myCAFs are contractile and stroma remodeling, whereas iCAFs express cytokines and chemokines indicative of their immunomodulatory and inflammatory role [132]. A third subpopulation of antigen-presenting CAFs, which expresses MHCII and has the capacity to present antigen to CD4+ T cells *ex vivo*, was later identified in mouse and human PDAC [133]. It was recently suggested that wound-associated signals from the tumor niche induce mesothelial cells to acquire features of apCAFs, which exert their unique immune-regulating role by promoting Treg formation and expansion through antigen-dependent TCR ligation [134]. Another study used mass spectrometry to analyze mesenchymal cell populations in normal and tumor mouse pancreatic tissue. There, CD105 was identified as a marker for two functionally different CAF populations. Importantly, both CD105-positive and CD105-negative cells displayed myCAF and iCAF gene signatures. However, functionally, the CD105-positive population was tumor promoting, while CD105-negative CAFs were tumor-suppressive.

Together, these studies question whether CAF subtypes represent truly distinct lineages or are a “snapshot” of CAF plastic states. Indeed, CAFs have been shown to respond to a wide variety of signaling cues. For instance, upon plating in 2D, iCAFs and apCAFs may revert to acquire a myCAF phenotype [132,133]. Additionally, JAK/STAT and TGF- $\beta$  signaling act antagonistically to induce CAF heterogeneity. It has been proposed that tumor cells secrete TGF- $\beta$  that inhibits IL-1R1 expression and JAK/STAT signal activation in adjacent CAFs, therefore promoting a myCAF phenotype. On the contrary, lack of TGF- $\beta$  in distal tumor areas leads to high IL-1R1 expression, which stimulates NF- $\kappa$ B signaling and activates the JAK/STAT pathway, therefore supporting the iCAF phenotype [133]. TGF- $\beta$  and IL1 can also promote transition of mesothelial cells to apCAFs [134]. Short-term inhibition of the Sonic Hedgehog pathway resulted in depletion of myCAFs and enrichment of iCAFs in orthotopic PDAC xenografts, suggesting that Hedgehog signaling may also be important for the maintenance of myCAFs [135]. In addition,

hypoxia could synergize with cancer cell–derived cytokines to induce an iCAF phenotype [136]. CAF heterogeneity, plasticity, and topography are best being addressed through the use of sc-RNAseq and spatial transcriptomics in a wide variety of cancers, including PDAC [133,137–142].

CAFs can affect tumor progression through different mechanisms—collagen deposition, ECM remodeling, and secretion of growth factors, cytokines, and chemokines [143–145]. Despite early proposals that CAFs promote tumor progression, experimental evidence suggests more varied and complex roles. For instance, deletion of  $\alpha$ -SMA+ fibroblasts in a mouse model of PDAC accelerated tumor progression and induced immunosuppression [146]. By contrast, genetic deletion or pharmacological targeting of FAP-expressing fibroblasts reduced tumor growth in mouse models of PC [147]. These findings indicate that CAFs might have both tumor-promoting and tumor-restraining roles, and they highlight the need to better understand their function. These observations support that, from a therapeutic standpoint, rather than “deleting” the tumor stroma, the aim should be to “normalize” its activity [148].

*Immune cells* are essential components of the PDAC TME. They include tumor-associated macrophages (TAMs), CD4+ and CD8+ lymphocytes, regulatory T cells (Tregs), dendritic cells, and myeloid-derived immunosuppressive cells (MDSCs). In PDAC, TAMs, Tregs, and MDSCs prevail over T cells and dendritic cells, thus creating an immunosuppressive microenvironment [149]. By releasing cytokines, proteases, and growth factors, these cells can promote tumor cell growth and blunt antitumor immune responses [150–153].

One of the first infiltrating cells in PanINs are TAMs [154,155], and their number increases during progression to invasive cancer. Several studies have demonstrated an inverse correlation between TAM infiltration and patient prognosis in different tumors, including PDAC [150,156]. TAM-derived cytokines and chemokines, such as IL1 $\beta$ , IL8, and CCL18, can promote the epithelial–mesenchymal transition (EMT) in cancer cells by activating signaling by PAR1 [157] and TLR4/IL10 [158]. Coculture of PC cells with M2-polarized TAMs favored a fibroblastic morphology, upregulated vimentin and SNAIL expression, and increased proliferation, migration, and metalloproteinase (MMP2) and MMP9 proteolytic activity in tumor cells [158]. In addition, TAMs can modulate the efficacy of chemotherapy in PDAC, affecting the activity of cytidine deaminase, a key metabolizer of gemcitabine, thereby driving resistance to this drug in *in vivo* PDAC models [159].

Another cell type contributing to immune suppression and inflammation in PDAC are myeloid-derived

suppressor cells (MDSCs). MDSC content correlates with clinical cancer stage [160]. Through direct cell-to-cell contact with T lymphocytes, MDSCs upregulate PD-L1, which can lead to the suppression of T cell activation and self-tolerance [161]. Moreover, MDSCs can stimulate the expansion of Tregs, which again results in suppression of T cell function [162]. Therefore, efforts have been made to develop strategies to eliminate both TAMs and MDSCs and improve antitumor immunity.

PDACs are believed to be nonimmunogenic or cold, showing low infiltration of CD8<sup>+</sup> cytotoxic lymphocytes (CTLs), which localize at the tumor border or are trapped within fibrotic tissue but are absent from the tumor core. CTLs produce IFN- $\gamma$ , TNF, and cytotoxic molecules, such as perforin and granzymes, which are major effectors in tumor rejection. In PDAC, CTLs most often show minimal activation [155,163]. Both cancer cells and inflammatory cells (e.g., MDSCs) play critical roles in regulating T cell function and can drive T cell exhaustion [164]. Exhausted T cells express high levels of inhibitory receptors, including programmed cell death protein 1 (PD-1), lymphocyte activation gene 3 protein (LAG-3), T cell immunoglobulin domain, and cytotoxic T lymphocyte antigen-4 (CTLA-4). Other characteristic of exhausted T cells is the loss of IL2 and granzyme B production and ex vivo killing capacity [165,166]. Reversing exhausted T cells and restoring antitumor potential have proven a valuable strategy to tackle cancer.

Altogether, an improved understanding of the normal and pathological stromal physiology, with CAFs and different immune cells, is essential to harness the therapeutic potential of a wide variety of drugs—including vitamin D.

#### 4. The biology of vitamin D in pancreatic cancer: experimental studies

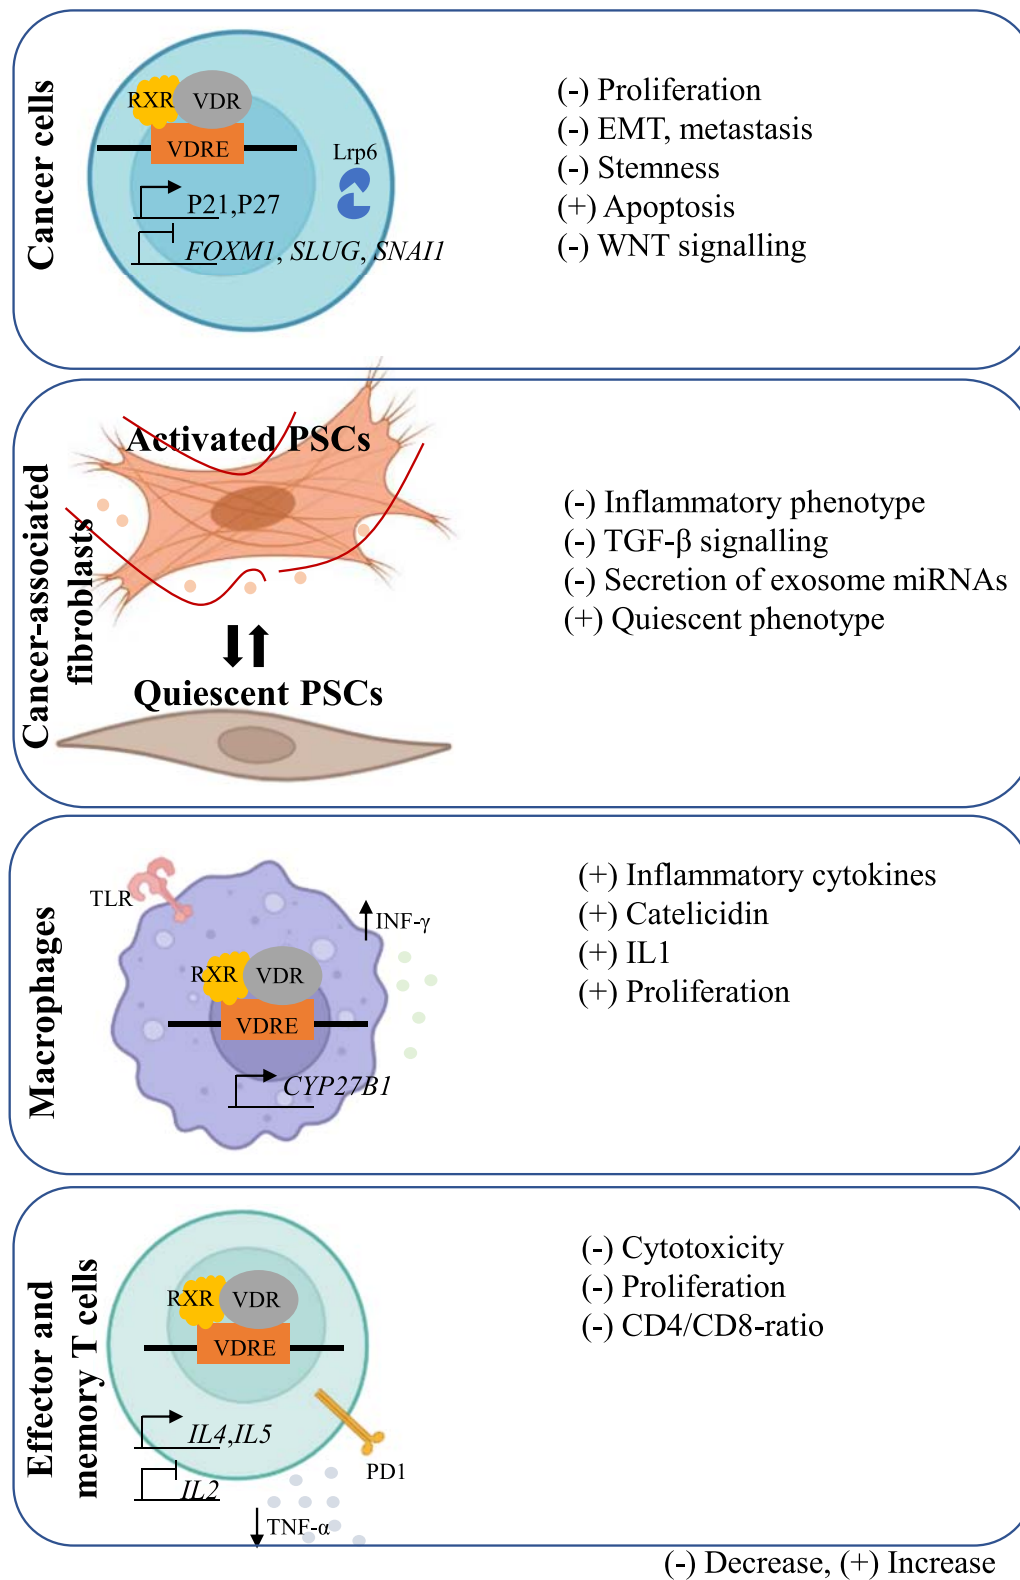

A summary of the main findings reported is shown graphically in Fig. 92.2 (Box 92.2).

##### 4.1 Vitamin D and pancreatic tumor cells

The expression of CYP27B1 and of VDR in various cell types promoted the idea that calcitriol might have autocrine and paracrine effects beyond its role in calcium homeostasis [167]. Indeed, both CYP27B1 and VDR are expressed in gut epithelial, immune, and cancer cells [168]. Recently, chromatin immunoprecipitation experiments have shown that VDR can bind to a large number of genomic sites, therefore controlling the transcription of many genes upon activation by ligand [169,170]. These experiments further support wider roles of vitamin D than initially believed.

VDR and its target gene *CYP24A1* are overexpressed in PDAC tumor cells, compared with adjacent nonneoplastic pancreas, concomitant with *CYP21A1* downregulation in tumor-associated islets. These findings suggest a dysregulation of the vitamin D system in PDAC [171]. Vitamin D can affect the biology of PC cells by different means. Early studies of the effect of vitamin D analogs on PDAC cells showed growth inhibition and G1 phase arrest [172–174], possibly through the upregulation of p21 and p27 and increased hypophosphorylated RB1 [175,176]. Moreover, the antiproliferative effects of vitamin D<sub>3</sub> have been reported to be mediated, at least in part, by inhibition of SMO and the Hedgehog (HH) pathway in a VDR-independent manner [177]. This cytostatic effect was restricted to cell types known to rely on an activated HH pathway. However, in this study, vitamin D<sub>3</sub> had no in vivo antitumor activity alone or in combination with 5-fluorouracil or gemcitabine, nor with irradiation. Beyond vitamin D, MART-10 (19-nor-2 $\alpha$ -(3-hydroxypropyl)-1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>)—a calcitriol analog—was found to inhibit the EMT and block migration and invasion of BxPC3 and PANC1 cells through downregulation of SLUG and SNAIL [178]. These effects were similar to those reported earlier in colorectal cancer [179]. These antiproliferative effects in vitro are paralleled by an inverse correlation between VDR and FOXM1 expression in PDAC cells and tissues: pharmacological and genetic activation of VDR signaling lead to reduced FOXM1 expression and promoter activity which suppressed tumor stemness, growth, and metastasis [180]. An additional mechanism by which vitamin D may impair PDAC growth includes a reciprocal feedback loop between VDR and WNT signaling through the downregulation of LRP6, a canonical Wnt ligand coreceptor, and transcriptional upregulation of LDLRAP1, associated with increased LRP6 receptor internalization and degradation and reduced WNT signaling [181]. A synthetic lethality screen to identify genes whose activity is required for gemcitabine sensitivity identified the VDR, though these effects might be ligand-independent and mediated by modulating DNA damage repair. Upon VDR disruption, a reduced number of phospho- $\gamma$ H2AX and RAD51 foci in response to gemcitabine was demonstrated suggesting that VDR inhibition might cooperate with genotoxic drugs [182]. Altogether, the few studies addressing the effects of vitamin D and its analogs on PDAC cells support their ability to directly target tumor cells to impair tumor growth, stemness, and metastasis.

The studies of the in vivo administration of VDR agonists on tumor growth have yielded discordant results [180,183,184]. These discrepancies are likely due to differences in the activity of the compounds used, the responsiveness of the cellular models, and the readouts applied. In vitro and in vivo experiments have shown

**FIGURE 92.2** Overview of the biological effects of vitamin D on pancreatic cancer cells and components of the tumor microenvironment.

## BOX 92.2

## Summary of the main experimental studies

- VDR and CYP24A1 are overexpressed in PDAC cells, compared with nonneoplastic pancreas.
- In vitro studies of the effects on PDAC cells indicate that vitamin D can inhibit (1) proliferation through p21 and p27, via the SMO/Hedgehog pathway and via a reduction of Wnt signaling through increased degradation of its canonical ligand LRP6 and (2) EMT, migration, and invasion via downregulation of SLUG and SNAI1.
- In vivo studies have yielded discordant results with significant antitumor activity being observed in some cases. Discrepancies might be due to heterogeneity in the cellular models used and differences in the activity of the compounds used.
- Vitamin D treatment of activated fibroblast attenuates the expression of cancer-associated signatures and reduces proliferation, migration, and release of protumoral exosomal miRNAs.
- 1,25(OH)<sub>2</sub>D suppresses proliferation of T lymphocytes and production of cytokines, shifting from a proinflammatory to a tolerogenic state.
- In a syngeneic PDAC model, calcipotriol treatment increased immune cell infiltration and decreased T cell exhaustion and amount of Tregs.

the synergistic effect of gemcitabine and calcitriol, mediated by increased apoptosis and inhibition of Akt signaling in Capan-1 cells [185].

## 4.2 Vitamin D and the pancreatic tumor microenvironment

In the following, we describe current knowledge on the impact of vitamin D on cancer-associated fibroblasts and the immune TME compartment.

### 4.2.1 Cancer-associated fibroblasts

Most of the studies investigating the effect of vitamin D on the pancreatic TME have focused on PSCs and CAFs. Therapeutic strategies that can revert or reprogram activated PSCs to their quiescent state may hold promise for more effective treatment options alone or in combination with agents targeting the tumor cell compartment. An important study showed that calcipotriol induced transcriptional reprogramming of activated PSC toward a quiescent state, suppressed secretion of inflammatory cytokines and growth factors, increased gemcitabine treatment efficacy in vitro, and improved survival in a murine model of PDAC. RNA sequencing of preactivated, culture-activated, and cancer-associated PSCs identified signatures associated with activation and/or cancer. Calcipotriol reduced the expression of lipid-storage genes and upregulated cell proliferation and adhesion [186]. These authors also found an upregulation of VDR signaling in activated PSCs and CAFs. Treatment of preactivated and activated PSC with calcitriol showed an inhibition of activation and suppression of cancer-associated signatures and reduced expression of negative regulators of

angiogenesis—such as Thbs1—and decreased TGF- $\beta$  signaling, in agreement with prior studies showing a cross-talk with the VDR [187]. VDR activation also attenuated PSC activation, inflammation, and fibrosis upon caerulein-induced pancreatitis. Altogether, these results strongly support a role of VDR in the regulation of PSC quiescence/activation both in vitro and in vivo. To explore the ability of calcitriol to modulate the tumor-stroma cross-talk, conditioned medium from activated PSC grown in the presence of calcitriol was added to tumor cells, resulting in reduced EMT activity, proliferation, and chemoresistance. When KPC mice, harboring a mutant *Kras* allele and *Trp53* inactivation in the pancreas, were treated with calcitriol and gemcitabine, an increased intratumoral concentration of gemcitabine was demonstrated, associated with a significant decrease in tumor volume and tumor-associated fibrosis [186]. This pioneered the potential benefit of stroma remodeling rather than stroma depletion. A subsequent study confirmed that calcipotriol reduced the release of IL-6, LIF, and PGE2 but had variable effect on  $\alpha$ SMA or podoplanin expression. Consistently, calcipotriol reduced CAF proliferation and migration. However, there were no significant effects on the capacity of CAFs to modulate the contractility of the collagen matrix. In a 3D coculture system including CAFs, PDAC cells, and T lymphocytes, calcipotriol upregulated PD-L1 expression and dampened the proliferation and functionality of CD8<sup>+</sup> T cells, indicating that VDR signaling can impact broadly on the tumor ecosystem [188]. A recent study showed that VDR activation abrogated the release of protumoral exosomal miRNAs (miR-10a-5p), affecting PDAC cell proliferation and migration [189].

#### 4.2.2 The immune TME compartment

Enzymes involved in vitamin D metabolism and the VDR are expressed in a wide variety of immune cells including lymphocytes, monocytes, macrophages, and dendritic cells [190,191]. Following the recognition that vitamin D can modulate the activity of the innate immune system in tuberculosis [192], its role in monocyte and macrophage activation emerged.  $1,25(\text{OH})_2\text{D}$  produced by monocytes/macrophages can exit the cell, suppress the proliferation of T lymphocytes, and modulate the production of cytokines and T cell differentiation, resulting in a dramatic shift from a proinflammatory to a tolerogenic state. The effects of  $1,25(\text{OH})_2\text{D}$  on the differentiation, proliferation, and functions of CTL are likely mediated by both direct activation of VDR and changes in cytokines signaling via T helper cells [193,194]. Other studies have reported that vitamin D can also affect the homing of T cells to specific tissues, such as lymph nodes [195].

Few studies have investigated the effects of vitamin D on the immune component of the PDAC-TME. A recent report showed that calcipotriol improved viral delivery and replication, increased immune cell infiltration, and decreased T cell exhaustion and Tregs in a syngeneic PDAC model using oncolytic viroimmunotherapy with recombinant orthopoxvirus (CF33) [196]. Increased CD8+T cell infiltration upon vitamin D treatment has been described in breast [197] and melanoma lung metastasis models [198]. However, the contribution of stromal cells to the effects on T cells has not been fully dissected [188]. PDAC cells can induce changes in intracellular  $\text{Ca}^{++}$  signaling and NF- $\kappa\text{B}$  activation that could be reverted by calcitriol in a SMAD4-dependent manner (PMID: 32679840). However, other studies in other tumors suggest tumor-promoting effects of calcitriol through enhanced M2 macrophage polarization, leading to increased cell migration.

Overall, the paucity of studies in PDAC calls for additional research before the full potential of modulation of VDR signaling is understood.

### 5. Vitamin D and prognosis in patients with PC

Most PC patients are diagnosed with locally advanced or metastatic disease, and only 20% of patients are candidates for radical surgery, which is the only option for cure. The 5-year survival rate of patients who are candidates for surgical resection is close to 25%. An important feature of PC is that even small tumors (<2 cm) are often metastatic, suggesting that PC becomes a systemic disease even at early stages [107,199].

The survival of patients with PC has increased slightly in the past decade, but there is a need for

breakthroughs in early diagnosis and treatment to reduce mortality. The lack of sensitive and specific tumor markers that would allow detecting the disease early makes screening for PC remains extremely challenging.

The association of low vitamin D levels with prognosis in patients with PC has been investigated by several studies with different designs, reaching variable degrees of evidence (see Table 92.2 for further details). Ecological studies support an association between vitamin D and higher survival rates in cancer patients. Five-year survival rates south of  $50^\circ\text{N}$  were 20%–50% higher than those near  $55^\circ\text{N}$ , using survival data from cancer patients (among them PC) diagnosed from 1990 to 1994 from nine European countries (Eurocare-3 study) [45]. Other studies have investigated vitamin D as a prognostic factor in PC patients using different biomarkers such as vitamin D, DBP levels, VDR or CYP24A1 expression, and SNPs tagging the VDR gene.

#### 5.1 Vitamin D levels

Studies have largely used plasma  $25(\text{OH})\text{D}$  levels as a preferred measurement because it has a 2-week half-life and it reflects both dietary intake and endogenous production [200]. However, the results are inconsistent (Table 92.2).

*Direct association.* Cho et al. [78] reported that in patients with advanced PC, deficient vitamin D levels were associated with worse prognosis (HR = 1.99,  $P$ -value = .01) in a multivariate analysis considering season and BMI as confounding factors. In a prospective study of 493 patients with PC from five large US cohorts, Yuan et al. [79] found that patients with sufficient levels of prediagnostic  $25(\text{OH})\text{D}$  had a 35% lower hazard for death compared with those who were vitamin D deficient. This association was even stronger among patients with blood collected within 5 years of diagnosis, with an HR of 0.58 (95% CI, 0.35–0.98).

*No association.* Van Loon et al. [81] found that baseline  $25(\text{OH})\text{D}$  levels were not associated with either progression-free survival or overall survival in patients with advanced PC who received systemic chemotherapy. McGovern et al. [83] found that baseline  $25(\text{OH})\text{D}$  levels did not associate with PFS or OS, either. Similar findings were reported by Haas et al. [82] in a prospective single-center study of pretreatment levels of  $25\text{-OH vitamin D}_3$  in patients with advanced PC and by Von Hoff et al. [84] in a post hoc analysis of the phase III MPACT trial in patients with metastatic PC. In the ATBC cohort study, including Finnish smoker males who developed PC, results suggest an improved survival for patients with higher serum  $25(\text{OH})\text{D}$  levels, but the association was not significant [80]. Considering

the natural history of PC, it is conceivable that vitamin D may have a limited impact on outcome once patients are diagnosed.

## 5.2 Vitamin D receptor

VDR influences the expression of several hundred genes, so that vitamin D and its effectors may affect up to 3%–5% of the human protein-coding genome [201]. The role of VDR in PC has been explored at the germline level and by assessing its expression in the tumor.

*Germline genetic variants.* The association of SNPs tagging VDR with overall survival has been assessed in several studies, with contradictory results. In 493 PC patients from five US prospective cohorts who were genotyped for 36 tagging SNPs in the VDR gene  $\pm 20$  kb, Yuan et al. [79] did not find any association with overall survival (OS). In contrast, Innocenti et al. [85] reported that patients with advanced PDAC treated with chemotherapy who were homozygous for the GG allele of the VDR-rs2853564 SNP had a significantly longer survival (10.6 months) than those who were heterozygous (8.2 months) or homozygous for the AA allele (6.6 months). An interaction with high pretreatment levels of 25(OH)D as well as with gemcitabine treatment was reported. The authors suggested that rs2853564 might be clinically relevant primarily in the presence of adequate vitamin D supply; this variant appears to associate with reduced IRF4 binding and increased transcriptional activity in reporter assays. Li et al. [77] found that VDR-rs2228570 significantly associated with pathological differentiation and VDR-rs1544410 with TNM classification. These findings need to be replicated in independent studies.

*VDR expression in PC:* Using IHC, Wang et al. [86] found that VDR was detected in normal pancreas, with higher expression in acinar and ductal cells than in the stroma. VDR expression was higher in well-differentiated and in smaller ( $<25$  mm) tumors (64% vs. 26%). Low VDR expression in tumors was associated with a poor prognosis. They hypothesize that VDR expression in the stroma could largely depend on the activation status of pancreatic stellate cells, acting as a regulator of the cross-talk between tumor and stroma [86]. Consistently, a 3.7-fold higher expression of VDR mRNA was found in PDAC compared with adjacent pancreas tissue [171].

## 5.3 Vitamin D–binding protein levels

DBP is involved in vitamin transport in plasma, among other functions. Abulaizi et al. [202] found that DBP plasma levels were significantly diminished in PC patients. Iuga et al. [87] analyzed nine patients and

found higher DBP expression in tumor than in normal tissue. Furthermore, they found an association of low DBP expression with reduced survival.

## 5.4 CYP24A1 expression

CYP24A1 is an essential component of vitamin D metabolism, through inactivation of 1,25(OH)<sub>2</sub>D by hydroxylation; it has been reported to be overexpressed in PC and in nonneoplastic adjacent areas from surgical resection specimens, with no association with survival. Trends for association with differentiation and lymph node metastases were reported [88].

## 6. Vitamin D intervention studies in patients with PC

Two clinical trials found significantly reduced all-cancer incidence for individuals taking vitamin D in addition to calcium, compared with placebo or calcium alone [203,204]. Clinical trials have also found that vitamin D administration is associated with reduced levels of biomarkers of inflammation [205]. However, a recent *post hoc* analysis of data from the Vitamin D Assessment trial concluded that a high-dose vitamin D supplementation prescribed monthly for up to 4 years without calcium may not reduce cancer risk [206]. None of these intervention studies has investigated specifically the incidence of PC, likely due to its low incidence.

The effects of the administration of vitamin D analogs in combination with chemotherapy have been assessed in several clinical trials (see Table 92.3 for further details).

*Seocalcitol*, also known as EB1089, was administered to patients with inoperable PC in a phase II clinical trial [89] based on promising preclinical evidence [86]. While well tolerated (the most frequent toxicity being dose-dependent hypercalcemia), there was no antitumor effect nor an improvement of patient survival.

*Calcitriol* (1 $\alpha$ ,25(OH)<sub>2</sub>D<sub>3</sub>). A phase II clinical trial including 25 patients with unresectable locally advanced or metastatic PC who received docetaxel concurrently with high-dose oral calcitriol showed a modest increase in time to progression (from 1.5 to 3.8 months) without improvement of OS [90].

*Vitamin D<sub>3</sub>.* High-dose vitamin D<sub>3</sub> (180,000 I.U. on day 1, followed by 4000 I.U. per day for 60 day) was administered to PC patients with vitamin D deficiency in a randomized phase 3 clinical trial (NCT03472833). The trial was terminated due to poor recruitment and follow-up during the Covid-19 pandemic, and the results of the study have not been reported.

*Paricalcitol (19-Nor-1 $\alpha$ ,25-dihydroxyvitamin D<sub>2</sub>)* is a synthetic noncalcemic, non-phosphatemic vitamin D analog. Nine clinical trials registered in Clinical Trials.gov (accessed August 22, 2022) evaluated the effect of paricalcitol in combination with chemotherapy in PC patients using different designs. NCT03331562, a double-blind randomized placebo-controlled phase II clinical trial, found no difference in survival in patients who had advanced PC and received systemic chemotherapy [81]. NCT03300921 was terminated because of results suggesting that paricalcitol may be harmful to a subset of PC patients and feasibility issues to subtype patients in the short time frame before surgery. NCT03519308 did not meet the accrual goal. Three clinical trials (NCT04617067, NCT03883919, and NCT03415854) are active although not recruiting, and NCT03520790 and NCT04524702 are currently recruiting patients with stage IV PC and advanced/metastatic PC, respectively.

*Dietary supplementation (curcumin, vitamin D, vitamin K2, vitamin K1, B-6, high selenium broccoli sprouts, epigallocatechin gallate, L-carnitine, garlic extract, genistein, zinc amino chelate, mixed tocopherols, ascorbic acid, D-limonene).* A feasibility pilot phase I trial (NCT02336087) is evaluating gemcitabine/abraxane plus metformin and a dietary supplementation including vitamin D in patients with unresectable PC. The study is active, although not recruiting, and no results have been posted.

## 7. Conclusions

The broad biological effects of vitamin D, and the evidence of associations with better health status, render vitamin D an attractive subject of study in PC. The studies reviewed here provide conflicting evidence on the association with risk, prognosis, and its possible effects in the postdiagnosis setting. Among the reasons of this lack of consensus among studies are the different geographical settings and UV light exposures, population heterogeneity, the distinct vitamin D-related compounds measured, the drugs/doses used for supplementation, as well as the heterogeneity of study designs, data collected, and analytical approaches applied.

Current knowledge supports the notion that reducing the proportion of individuals with inadequate levels of vitamin D in the general population may impact on reducing the risk of PC, possibly by lowering the impact of risk factors associated with this tumor. However, formal evidence needs to be acquired, and intervention studies should be the best approach to address these questions. The latter should focus on the PC high-risk subjects with insufficient/deficient levels of vitamin D, also possibly considering their genetic profile. On the

other hand, the advanced stage at which patients with PC are diagnosed, their advanced aged, and the low performance status of many patients complicate the study of the impact of vitamin D supplementation in the post-diagnosis setting. The experimental work conducted in the past few years strongly supports the notion that vitamin D may effectively modulate the activity of the tumor stroma, and this could contribute to enhance the antitumor activity of the immune system, increase drug delivery, and improve patient outcome. This requires the conduct of well-designed clinical trials incorporating a panoply of biomarker analyses that allow acquiring mechanistic insight to optimize the use of this hormone.

## 8. Summary points

- Overall, there is not sufficient evidence supporting that primary, secondary (e.g., screening for vitamin D deficiency and vitamin D supplementation), or tertiary prevention strategies should be applied to reduce PC incidence.
- In vitro and in vivo studies support the notion that vitamin D can affect the phenotype and biological behavior of both tumor cells and the tumor microenvironment.
- More work is needed to establish the potential of vitamin D to reduce the medical impact of PC.

## Acknowledgments

Work in the authors' laboratories is supported, in part, by grant RTI2018-101071-B-I00 from Ministerio de Ciencia, Innovación y Universidades (Madrid, Spain) (cofunded by the ERDF-EU) to FXR and grant PI18/01347 from Fondo de Investigaciones Sanitarias (FIS), Instituto de Salud Carlos III (Madrid, Spain) to N.M. S.Z. is recipient of a grant from the Marie Skłodowska-Curie Program of the European Commission (PDASwITCh-895943). CNIO is supported by MCIU as a Centro de Excelencia Severo Ochoa (grant SEV-2015-0510). We thank A. Muñoz for critical review of the chapter and valuable suggestions.

## OBJECTIVES

- Present the ways in which skin can adapt to UV exposure and note the similarity of the action spectra for vitamin D synthesis and skin cancer production.
- Describe the main forms of UV-induced DNA damage, how the DNA damage is repaired, and the role of UV-induced immune suppression in photo-carcinogenesis.
- Outline the ways in which the vitamin D system in skin, comprising vitamin D-related compounds and receptors, modify skin cancer development and outcomes.
- Present the proposed mechanisms by which vitamin D compounds reduce UV-induced DNA damage with emphasis on reductions in reactive oxygen and nitrogen species, increased energy provision, increased DNA repair proteins and activity and the receptors involved.
- Discuss the role of vitamin D compounds in modifying UV-induced inflammation and immune suppression and other factors that contribute to skin cancer development.

pressure and of course, vitamin D synthesis [1]. The downside is that sunlight exposure is a major factor in the development of skin cancers, both keratinocyte and melanocyte-derived cancers [2]. Solar ultraviolet (UV) radiation contains UVA, UVB, and UVC. UVC ( $\lambda$  100–290 nm) is mostly removed by the ozone layer. UVB ( $\lambda$  290–320 nm), normally around 5% of total UV in sunlight and UVA ( $\lambda$  320–400 nm), comprising the remaining 95% of solar UV radiation, are major skin carcinogens that penetrate the epidermis and part of the dermis [3]. UV radiation produces DNA damage directly and via reactive oxygen and nitrogen species and causes immune suppression. While mild immune suppression may actually have benefits in reducing the risk of some autoimmune diseases [4], the combination of DNA damage and immune suppression is essential to the formation of skin neoplasms [5,6].

## 1.1 Sunlight and skin cancers

The most common type of skin cancer, basal cell carcinoma (BCC), is derived from keratinocytes, as is the rather less common, but potentially metastatic, squamous cell carcinoma (SCC), while the uncommon, but potentially deadly cutaneous malignant melanoma (CMM) is derived from melanocytes [7]. The incidence of skin cancers increases with age. For countries with large Caucasian populations living in tropical and temperate areas, such as the United States and Australasia, skin cancers are not only the most numerous type of cancer, but also the most costly to the health system [7,8].

The relationship between sun exposure and development of skin cancers is complex. Greater total

## 1. Introduction

Sunlight is essential for life on earth. Apart from providing energy for photosynthesis, light and heat, in human physiology, sunlight exposure has many positive effects on circadian rhythm and mood, blood

occupational or leisure UV exposure increases the risk of keratinocyte-derived skin cancer [7]. In general terms, increased sun exposure leads to increased SCC, whereas the relationship is less direct with BCC [7,9]. There is some evidence in European populations that cumulative sun exposure hours increase the risk of BCC up to a plateau, with little further increase in risk with further exposures, although the relationship depends on skin type [9]. Sun exposure that is “intermittent,” which includes high exposures at weekends or holidays, tends to be associated with increased risk of CMM and to some extent BCC [7]. The risk of all skin cancers is increased by sunburn at any age, with the largest effect on melanoma incidence, followed by BCC and then SCC [7,10]. There is epidemiological data showing that the risks of all major skin cancers are reduced by half in relatively light-skinned people who migrate from a low UV environment to a high solar UV environment, like Australia, after the age of 10 years, compared with people who lived all their lives in a high solar UV environment [11]. Having light skin, Fitzpatrick’s type I or II [12] increases the risk of all types of skin cancer, while ability to tan reduces the risk, mostly for SCC followed by BCC and then melanoma [7]. SCC and BCC tend to occur on chronically sun-exposed areas such as the face, ears, neck, and back of the hands, while melanomas occur in these areas but also on shoulders, backs, and limbs and sometimes on palms and soles [13], though the pathogenesis of melanoma in non-sun-exposed areas appears to be different [14,15].

## 1.2 Adaptation to UV

As sun exposure gradually increases after winter, there are several mechanisms that allow skin to adapt to UV exposure and protect against UV-induced damage. These include an increase in production of melanin, which is transferred to keratinocytes and provides a shield over the nucleus [16]. Even in people who do not tan well, the outer cornified layer of the epithelium (stratum corneum) can thicken markedly as a result of UV exposure, leading to a reduction in UV transmission [17]. Over recent years, accumulating evidence, also discussed in Chapter 25 (Bikle & Demay), indicates that there is another UV-adaptive mechanism in skin: the vitamin D system, including the vitamin D receptor (VDR) and local vitamin D synthesis and metabolism that generates 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}_3$ ) and other related compounds [18–21]. These vitamin D compounds, working at least in part via the VDR, contribute to reductions in UV-induced DNA damage and to reduced UV-induced immune suppression, at least in some mouse models, leading to reduced photo-carcinogenesis in mice [2,22–26].

## 1.3 Similarity of action spectra for vitamin D synthesis and skin cancer

It has been noted by Thompson and colleagues [27] that while the action spectrum for pre-vitamin D synthesis may differ slightly at low wavelengths from that for erythema, the empirically derived Skin Cancer Utrecht-Philadelphia-human (SCUP-h) spectrum [28] is remarkably similar to that for vitamin D synthesis *in vitro*, at least in the UVB range up to 315 nm (Fig. 93.1) [27]. Recent work on the UV action spectrum to increase blood 25-hydroxyvitamin D<sub>3</sub> ( $25(\text{OH})\text{D}_3$ ) in human subjects indicates a left shift of around 5 nm [29]. If anything, this increases the overlap of the vitamin D and skin cancer action spectra. Any exposure to UVB, necessary to convert 7-dehydrocholesterol into previtamin D (see Chapter 3), results in DNA damage, measurable as excised thymine dimers (see Section 3) in urine [30]. Nevertheless, in the middle of the day, when the UVB to UVA ratio is around its highest level, and a reasonable body surface area is exposed, equivalent to wearing short sleeves and shorts, UV exposure times for vitamin D synthesis are much less than for erythema for most light skin types [31]. Due to the degradation of pre-vitamin D and vitamin D by further exposure to UV, short frequent exposures to UV are more efficient for vitamin D synthesis and at the same time reduce erythema risk [31].

As also discussed in Chapter 25 and in this chapter, there is evidence that the vitamin D system, vitamin D compounds, and possibly the unliganded VDR [18,32] contribute to protection from all the major types of skin cancers (SCC, BCC, and CMM) [2,33].

## 2. UV-induced DNA damage, repair, and immune suppression

### 2.1 Direct DNA damage by absorption of UV

Two primary DNA lesions formed in human skin as a direct consequence of absorbing energy from UV photons are cyclobutane pyrimidine dimers (CPDs) and 6-4 photoproducts. CPDs occur when UVB cleaves DNA between carbon-5 and carbon-6 of adjacent pyrimidines. Subsequent dimerization of these pyrimidines produces a stable ring structure (Fig. 93.2). The majority of CPDs occur at thymine–thymine pairs resulting in thymine dimers. Thymine–cytosine and cytosine–cytosine dimers are also formed, at a rate proportional to that of thymine–thymine dimers, but with lower frequency, as they require more energy to produce [34,35]. The stable ring configuration of CPD and the relatively small degree of distortion of the DNA strand make this structure hard to detect and repair [36,37]. 6-4 photoproducts have a stable bond between positions 4 and 6 of adjacent pyrimidines and

**FIGURE 93.1** Action spectra describing UV dose-dependent response relationships for skin cancer, erythema, and cutaneous vitamin D production. SCUP-h, Skin Cancer Utrecht-Philadelphia-human.

occur at a much lower frequency than CPD [34]. These 6-4 photoproducts cause more helix distortion than CPD, which may be one reason that they are repaired more rapidly after UV exposure [36,37]. For these reasons, CPDs are the most frequent promutagenic DNA photoproducts in human skin [38]. Although the high energy of UVB and its ready absorption by DNA is considered necessary for the production of CPD, it has been reported that CPD can be produced by less energetic UVA radiation, apparently by direct absorption [35,39,40]. Generation of CPD may actually explain a considerable part of the mutagenic effects of UVA [41].

Inefficient repair of CPD and 6-4 photoproducts can result in mutations in the DNA sequence known as UV “signature” mutations [38,42]. If there are unrepaired UV-induced lesions in DNA during the S-phase of the cell cycle, the error-prone DNA polymerase-eta (a translesion polymerase) mainly inserts an adenine (A) by default, opposite lesions on the template strand that it cannot interpret, such as bulky dimers. This means that photoproducts, mainly CPD and less commonly 6-4 photoproducts, generate a characteristic C to T transition mutation. If the lesions are CC CPD, a CC to TT transition occurs, because two A residues are placed opposite the dimer by default in the place of two guanine (G) residues [43]. Although considered to have less mutagenic potential than other dimer types, there is evidence that the most common CPDs, thymine dimers, are indeed mutagenic [35,41]. CPDs are responsible for most of the mutagenic effects of UVB [37,38].

## 2.2 Indirect DNA damage by UV

UV exposure (both UVB and UVA) also generates reactive oxygen species, such as superoxide,

singlet oxygen, and the hydroxyl radical [44]. Nitric oxide and its products are also greatly increased in skin as a result of UV exposure, mainly through enzyme-independent release from preformed stores, for example, by UVA photodecomposition of nitrosothiols and nitrite, and partly through increases in inducible nitric oxide synthase (iNOS) [45,46]. Two major intermediates of the nitric oxide pathway, nitrous anhydride and peroxynitrite, are powerful nitrating and oxidizing agents formed when nitric oxide combines with oxygen or superoxide, respectively [47]. Oxidation of the primary amine of guanine generates predominantly 8-oxo-7,8-dihydro-2'-deoxyguanine (8-oxoguanine) (Fig. 93.2), which is typically associated with G to T transversions, and thus mutagenic if not properly repaired [44,48]. Reactive nitrogen products, including peroxynitrite, can also combine with guanosine to form 8-nitroguanine [49] (Fig. 93.2). Residues of 8-nitroguanine undergo rapid depurination to form a basic sites, which are promutagenic [50]. Deamination of purine and pyrimidine bases by nitration of primary amines by nitrous anhydride leads to DNA strand breaks [51]. DNA replication across noncoding sites of unrepaired base modifications can result in deletions, base mispairing, or substitutions where adenine is the default base added [43]. Nitrative deaminations generate C to T transition mutations in isolated DNA [51]. G to T transversions are typically associated with the 8-oxoguanine lesions in the tumor suppressor protein p53 and correlate with malignant transformation in skin photo-carcinogenesis [38]. Predominantly, C:G to T:A transversions, which cause inactivating mutations in p53, have also been reported in isolated DNA exposed to peroxynitrite [52].

**FIGURE 93.2 DNA damage by UV exposure.** Cyclobutane pyrimidine dimers are formed by direct absorption of UVB or UVA photons or less commonly by energy transfer from excited electrons. UV generates reactive oxygen and reactive nitrogen species, which oxidize or nitrate guanine bases. If improperly repaired, all of these changes in DNA can lead to mutations. DNA (6-4) photoproducts and single- or double-strand breaks are not shown. Reproduced from Ref. [27] with permission.

Indirect mechanisms may also contribute to generation of CPD. CPDs, termed "dark CPDs," are generated in melanocytes for 3 h after exposure to UVA [53]. These "dark CPDs" could be generated when UVA-induced reactive oxygen and nitrogen species excite an electron in melanin to create a quantum triplet state that has

the energy of a UV photon and is thus able to induce CPD by energy transfer [53]. The authors observed this effect in melanocytes, but proposed that a similar process and time course might be observed in keratinocytes [54,55], as keratinocytes too could contain melanin as a result of transfer of melanosomes from melanocytes [16].

## 2.3 DNA repair

DNA repair pathways include nucleotide excision repair (NER), base excision repair (BER), mismatch repair, double-stranded break repair, and photoreactivation. The pathway that is activated depends on the primary DNA lesion and the species [43]. Photoreactivation, which repairs CPD on a single strand of DNA, relies on an efficient enzyme, photolyase, which uses energy from the violet/blue end of visible spectrum. Photolyase does not seem to be active in placental mammals [56].

### 2.3.1 Nucleotide excision repair

In placental mammals, including humans, UV-induced pyrimidine dimers and 6-4 photoproducts are predominantly repaired by nucleotide excision repair (NER), a complex mechanism involving around 30 proteins [57]. The significance of this repair pathway in skin cancer is highlighted by the inherited recessive disorders xeroderma pigmentosum and Cockayne syndrome, in which there are mutations in genes encoding DNA repair or repair-related proteins, leading to defects in an aspect of nucleotide excision repair [58]. These patients have up to a 1000-fold increased incidence of skin cancer [59]. The first step in NER is carried out by damage recognition proteins which have the ability to identify small areas of damaged DNA from the vast amount of undamaged DNA. Two sub-pathways of NER have been identified, transcription-coupled repair and global genomic repair. The main difference between transcription coupled repair and global genomic repair lies in the initial damage recognition steps. Transcription-coupled repair involves removing lesions from the active transcribing strand of DNA, with RNA polymerase II as the initial damage sensor. The global genomic repair pathway repairs photolesions from any position of the genome through use of several damage recognition proteins as the initial damage sensor [57,60]. Repair of CPD is surprisingly slow, with appreciable numbers of CPD apparent > 24 h after UV exposure [35,37] and with even slower repair being evident for UVA-induced CPD compared with those produced by UVB [37]. This may be because as well as being pro-mutagenic, ROS produced by UVA inhibit nucleotide excision repair [61]. Overproduction of nitric oxide can inactivate DNA repair enzymes [61]. Other reactive oxygen/nitrogen molecules, such as peroxynitrite, are also pro-mutagenic and preferentially inhibit the excision and ligation steps of nucleotide excision repair [62], while conversely, NOS inhibitors enhance DNA repair mechanisms [63].

The first process in DNA repair is recognition of the lesion. Xeroderma pigmentosum (XP) complementation group C protein (XPC) is a versatile sensor of DNA structural distortions that, in turn, are critical to trigger repair [57]. The XPC protein complex is not particularly effective,

on its own, for detecting CPD, as opposed to other types of damage, probably because of the relatively small distortion of the DNA helix by CPD. The initial detection of CPD depends on UV-damaged DNA-binding protein (UV-DDB), which is a heterodimer of DDB1 (XPE-binding factor) and DDB2 (part of XPE) and associated proteins. In particular, DDB2 has been shown to directly interact with UV-induced dipyrimidine photoproducts. This binding of UV-DDB, in turn, recruits XPC and the rest of the nucleotide excision repair pathway [64]. Human cells with XPE mutations show profound defects in the repair of CPD [57]. Transcription-coupled repair is initiated by a stalled RNA polymerase II, which, in turn, recruits Cockayne syndrome proteins, CSA and CSB, to facilitate further assembly of the transcription-coupled NER complex [57,59].

After initial damage recognition, both pathways converge on a common step that depends on XPA as part of a much larger protein complex. The transcription initiation factor IIH (TFIIH) complex, which unwinds the damaged DNA double helix, consists of 10 protein subunits. These include two TFIIH basal transcription factor complex helicase subunits, XPB and XPD. These two proteins are involved in extending the opening of the DNA strands around the damaged lesion, but XPD is especially critical for verification of DNA damage. It is worth noting that transactivation of certain genes via the VDR is also mediated by TFIIH [65]. Full opening of the helix is further assisted by XPA, XPG, and the single-strand binding protein replication protein A (RPA). Further damage verification is carried out by XPA, which can detect nucleotides with distorted chemical structures in single-stranded DNA. The damage site in the single strand is incised at the double-strand junction by endonucleases ERCC1-XPF complex and XPG. DNA polymerase synthesizes a single DNA strand to fill the gap in the incised strand. Finally, DNA ligase seals the nick in the DNA strands [57]. This conservative and highly specific pathway ensures that the UV-damaged photolesions are removed from the genome, but if the damage is extensive, cells undergo apoptosis.

### 2.3.2 Base excision repair

Oxidative DNA damage and nitrative DNA damage are eliminated by base excision repair (BER) [44,48,66]. The repair enzyme human 8-oxoguanine-DNA glycosylase 1 (Ogg1) is less abundant in the basal layers than the superficial layers of the skin, however, which indicates that repair of oxidative damage in the dividing cells of the epidermis is less efficient [44]. Base excision repair is more rapid than NER [67]. Initial damage recognition and the removal of the damaged base are carried out by Ogg1 or alkyladenine DNA glycosylase for RNS-modified DNA [68]. After damage recognition, the same enzyme catalyzes cleavage of the N-glycosidic

bond between the base and the 2′deoxyribose sugar molecule to remove the damaged base. The removal of the damaged base from the strand forms an abasic site known as an apurinic/apyrimidinic (AP) site. The DNA backbone of the abasic site is incised by a DNA AP endonuclease or DNA AP lyase to form a 5′ single-strand nick at the AP site. The gap in the DNA strand is filled with the correct complementary base by DNA polymerase. After this, a DNA ligase completes the repair by sealing the nick in the DNA helix [48,66].

## 2.4 UV-induced immune suppression

Immune responses in the skin that would be expected to detect and prevent the development of tumors in skin are suppressed by even low or single doses of UV [63,69,70]. The importance of suppression of adaptive immunity in the pathogenesis of skin tumors was demonstrated by the pioneering work of the Kripke group. UV-induced tumors transplanted into UV-irradiated mice continued to grow, whereas they were rejected in un-irradiated mice [5,6]. The vastly increased risk of skin cancer development, particularly SCC and to some extent BCC, in immunosuppressed people, such as those who have received organ transplants [71,72], is further key evidence for a role of immune suppression in skin cancer development.

Pyrimidine dimers are important mediators of photo-immune suppression [63,73]. Exposure of UV-irradiated opossums to visible light, which activates the pyrimidine dimer repair enzyme photolyase, resulted in a reduction in CPD and in immune suppression [74]. Photoimmune suppression was also reduced in irradiated mice and in human subjects after reduction of CPD by application of encapsulated T4 endonuclease, the specific repair enzyme for pyrimidine dimers [63,73].

Exposure to UV results in a substantial reduction in numbers of Langerhans cells, which normally are involved in immune surveillance in the skin, as well as reducing the antigen-presenting ability of those remaining [70,75]. Mediators of photoimmune suppression include increased immunosuppressive cytokines such as interleukin (IL)-10 from keratinocytes and mast cells [76,77], increased proinflammatory cytokines such as IL-6 [78,79], and suppressed immune-stimulating cytokines such as IL-12 [80]. *Cis*-urocanic acid formed by UV isomerization of the photoreceptor *trans*-urocanic acid located in the outermost layers of skin also inhibits the antigen-presenting propensity of Langerhans cells [81]. The peroxidation of lipids by ROS such as peroxynitrite has been implicated in release of cytokines, which in turn modulate regulatory T cells and indeed regulatory B cells, suppressing immune responses at distant sites [77,80]. T regulatory cells help

maintain a balance between immunosuppression and autoimmunity [77]. These cells are present in skin as well as skin draining lymph nodes and therefore could also be subjected to DNA damage and oxidative stress. Antioxidant treatment has been shown to abolish immune suppression mediated by the lipid peroxidation pathway in irradiated mice [82]. Mast cells are clearly important for the development of UV-induced immune suppression since UV exposure does not suppress immunity in mast cell-deficient mice [83]. This may be partly due to migration of mast cells in skin, activated by UV-induced platelet activating factor, to B cells in draining lymph nodes. If this migration is blocked, there is no UV suppression of T cell-mediated immunity [83].

Both UVB and UVA components of sunlight are immunosuppressive in mice and humans [84–88]. Although certain wavelengths of UVA have been shown, at least in some systems, to have a protective effect against UVB-induced immunosuppression in mice [86], there is conflicting data in animals and human subjects [85–87,89]. A further complication is that UVA and UVB have interactive effects that are not just additive. When given separately to humans, low-dose UVA and UVB were not immune suppressive 3 days after exposure, but when the same overall dose was delivered as solar-simulated UV, it caused potent immune suppression [84]. Most people are normally exposed to sunlight that contains both UVA and UVB.

UV exposure suppresses both contact hypersensitivity reactions and delayed-type hypersensitivity reactions to viral, bacterial, and fungal antigens and causes both local and systemic suppression of the adaptive immune system [1]. This immune-suppressive effect is greater in male mice and male humans [90,91]. While excessive UV exposure promotes the development of skin cancers, mild UV-induced immune suppression may help maintain immunological self-tolerance, through the actions of T regulatory cells, UV-B regulatory cells, mast cells, and IL-10 [1]. In contrast to its effect on adaptive immunity, UV exposure boosts innate immunity, possibly in part, due to production of vitamin D and its metabolites [92,93].

In summary, as outlined before, both UV-induced DNA damage, of various types, if not properly repaired, combined with UV-induced immune suppression together lead to photo-carcinogenesis [43].

## 3. The vitamin D system and skin cancers

### 3.1 Synthesis and metabolism of vitamin D compounds in skin

The photosynthesis of vitamin D<sub>3</sub>, via the intermediate, previtamin D<sub>3</sub>, which, at body temperature,

**FIGURE 93.3** Production and metabolism of vitamin D<sub>3</sub> and related compounds in skin. Previtamin D is synthesized when the B-ring of 7-dehydrocholesterol is broken upon the absorption of a photon of UVB. At body temperature, previtamin D is converted to vitamin D<sub>3</sub>. Continued absorption of UV photons by previtamin D or vitamin D<sub>3</sub> results in conversion to overirradiation products such as lumisterol<sub>3</sub>, tachysterol<sub>3</sub>, or suprasterols or 5,6-transvitamin D<sub>3</sub>. Vitamin D<sub>3</sub> is converted in skin to 25-hydroxyvitamin D<sub>3</sub> by CYP2R1 (or possibly CYP27A1) and then to 1,25-dihydroxyvitamin D<sub>3</sub> by CYP27B1. The cholesterol side-chain cleavage enzyme CYP11A1 is also expressed in skin and upregulated by UV. It can convert vitamin D<sub>3</sub> into 20(OH)D<sub>3</sub> and at least 10 other products. CYP11A1 can also convert lumisterol<sub>3</sub> into 24-hydroxylumisterol<sub>3</sub> and several other lumisterol derivatives.

isomerizes into vitamin D<sub>3</sub> has been described in Chapter 3. Vitamin D<sub>3</sub> from skin is absorbed into the blood by a process that requires vitamin D-binding protein (DBP) [94]. The classical pathway for activation of vitamin D<sub>3</sub>, via 25-hydroxylase activity to 25(OH)D<sub>3</sub> and then to the active hormone, 1,25(OH)<sub>2</sub>D<sub>3</sub>, has been reviewed in Chapter 4. All these reactions have also been shown to occur in skin [95–97], including the production of 1,25(OH)<sub>2</sub>D<sub>3</sub> in human skin in vivo [96]. The production of vitamin D<sub>3</sub> and its subsequent metabolism takes many hours in skin [95]. Absorption of additional photons by pre-vitamin D leads to the generation of so-called “over-irradiation products” such as lumisterol and tachysterol [98]. Less well known is that another CYP450 enzyme, the cholesterol side-chain cleavage enzyme CYP11A1, is also active in skin, and its expression is increased by UV [99–101]. CYP11A1 also hydroxylates the side chain of vitamin D<sub>3</sub> in vivo, to produce over 10 novel products [100]. 20-Hydroxyvitamin D<sub>3</sub> (20(OH)D<sub>3</sub>) is the major product of vitamin D<sub>3</sub> metabolism by CYP11A1 [99]. 20(OH)D<sub>3</sub> is present in serum at concentrations about 20-fold less than those of the major circulating D metabolite, 25(OH)D<sub>3</sub>, compared with 1000-fold less for 1,25(OH)<sub>2</sub>D<sub>3</sub>. CYP11A1 also metabolizes lumisterol<sub>3</sub> to 24-hydroxylumisterol<sub>3</sub> (24(OH)L<sub>3</sub>) and several other related compounds, which have biological activity, at least in some systems [102] (see Fig. 93.3). This is discussed in greater detail in Chapter 6.

### 3.2 Relationships between the vitamin D system and the three main types of skin cancers

There is accumulating evidence that the vitamin D system (metabolites and receptor) in skin contributes to reductions in both keratinocyte- (BCC and SCC) and melanocyte-derived (melanoma) tumors (see also Chapter 25). The critical UV-induced alterations that result in photo-carcinogenesis—DNA damage that is not repaired properly and immune suppression—contribute to the development of all types of skin tumors. In relation to melanocytes, it appears that inadequately repaired DNA damage produced by both UVB and UVA, together with UV-induced immune suppression, contributes to the pathogenesis of melanoma, particularly on sun-exposed skin [103,104]. Inadequately repaired DNA damage in melanocytes may lead to mutations or amplifications of genes involved in a variety of growth and survival pathways, such as BRAF, Kit, and cyclin D1 [105]. Melanocytes are different from keratinocytes in that they do not proliferate much and have reduced DNA repair capacity, but tend to be more resistant to apoptosis, despite significant DNA damage. These differences may help to explain the somewhat different patterns of UV exposure associated with melanoma compared with SCC [106,107]. Studies in transgenic mice indicate an interaction between β-catenin and the vitamin D system in skin, which, when

disrupted, promotes BCC development [19]. DNA damage, which results in activation of the Hedgehog (Hh) signaling system, tends to result in BCC [108]. Overexpression of elements of Hh signaling has been reported in the epidermis and epidermal portion of hair follicles of adult  $VDR^{-/-}$  mice [109]. The Hh signaling, which involves Patched (Ptch), glioma-associated oncogene homolog (Gli1), and smoothened (Smo), has been shown to regulate cellular functions that are of importance for embryonic development and carcinogenesis [109]. It is now well accepted that mutations in the Ptch gene are a key event of BCC carcinogenesis [109]. Interestingly, it has been demonstrated that vitamin D compounds inhibit proliferation and growth of BCCs of Ptch mutant mice in vitro and in vivo via the VDR [109]. Several of the genes of the Hh pathway have sequences consistent with VDR response elements [33]. There is also consistent evidence that un-hydroxylated vitamin  $D_3$ , including the vitamin  $D_3$  produced as a result of UV exposure, inhibits Hh signaling in mouse skin [110], as well as UV-induced BCC in transgenic mice [111].

Higher baseline vitamin D status, assessed by blood concentrations of 25(OH)D, is mostly associated with higher incidence of skin cancers, BCC, SCC, and even in some cases of CMM [112] though some studies show an inverse [113] or no association [112]. There is, of course, considerable confounding due to sunlight exposure [114]. Whether keratinocyte and melanocyte cancers would be more prevalent without the protective effect of the vitamin D system in skin is unknown. One prospective study, which examined a single measurement of serum 25(OH)D in subjects in an Australian subtropical community and determined skin cancer risk over the subsequent 11 years, found no evidence that vitamin D status counteracted high sun exposure [115]. In the Women's Health Initiative Trial, those with a history of nonmelanoma skin cancer who were randomized to calcium (1000 mg) and vitamin D (400 IU/day) had a reduced risk of melanoma, though this was not seen in the whole cohort [116].

In contrast, lower 25(OH)D concentrations around the time of diagnosis in melanoma patients are associated with thicker tumors (higher Breslow thickness) [117,118], more ulceration and higher mitotic rate [119], and overall worse outcomes such as increased risk of progression and death over the following 5 years [112,117,120–122] and reviewed in Slominski et al., [123]. Whether supplemental vitamin D as adjuvant treatment would improve melanoma prognosis is unclear. One clinical trial was established as a pilot to examine safety of large initial vitamin D dose in melanoma patients at time of diagnosis with subsequent monthly doses [124] (Australia and New Zealand Clinical Trials Registry (ANZCTR) ACTRN12609000351213). Although the large and intermittent vitamin D dosing

may not have been ideal for a vitamin D effect [125,126], the trial found no safety issues, but was not powered for a clinical outcome (R. Saw—personal communication). A trial of adjuvant vitamin D supplementation (100,000 IU/50 days) after resection of a stage II melanoma found that Breslow thickness ( $< 3$  mm vs.  $> 3$  mm) was the primary determinant of disease-free survival with no significant effect of vitamin D supplementation, though 25(OH)D increased significantly less in patients with a Breslow score  $> 3$  mm [127]. Another clinical trial established to examine this question [128] (Clinical Trial.gov, NCT01748448, December 05, 2012) has not reported to date.

VDR (*Vdr*) knockout mice have been reported to develop increased skin tumors, mostly papillomas or BCC, after exposure to oral [129,130] or topical [131] DMBA. *Vdr* knockout mice are also more susceptible to tumor formation, papillomas, and increased SCC after chronic UV radiation [130]. Although there are many studies of associations between VDR polymorphisms and risk of keratinocyte cancers, there is little consistency between the various reports [21]. Polymorphisms in the *VDR* gene have been associated with risk or prognosis of BCC [132–134], SCC or its precursor, actinic keratoses [135,136], and melanoma [137–140] or nevi [141], though not all studies have shown significant associations.

In relation to melanoma, though there is considerable inconsistency, overall, the *F* allele in *Fok1* is associated with a small (18%) increased risk for melanoma reviewed in Refs. [112,142], while the *B* allele of *Bsm1* is associated with a small (15%) decreased risk of melanoma, at least in some studies [143] and reviewed in Refs. [112,123,142]. Studies of *VDR* polymorphisms have produced highly variable results, but it seems that polymorphisms that are significantly associated with risk for melanoma mostly do not overlap with those related to melanoma survival [144] although other studies indicate some overlap [142]. Furthermore, the same polymorphisms such as rs73005032 can be associated with worse survival but lower melanoma risk [144]. VDR expression was lower in melanoma tumors than in normal skin and decreased with advanced tumor type [145]. Decreased nuclear VDR staining was associated with dermal invasion and metastasis [146]. In a study of over 3500 patients with melanoma, one functionally important VDR SNP—rs2239182, in the coding region of the *VDR* gene—was significantly associated with melanoma-specific death after adjustment for multiple testing [144]. Importantly, neither this SNP nor others found on primary analysis in that study were associated with Breslow thickness, ulceration, or mitosis [144]. VDR is induced in human skin with UVB exposure, at least at some doses, though not all [147], and in mouse skin and mouse skin explants [148].

Topical application of  $1,25(\text{OH})_2\text{D}_3$  inhibited chemically induced skin tumor formation [149]. Topical application of  $1,25(\text{OH})_2\text{D}_3$  also reduced skin tumors, including SCC, induced by chronic UV exposure [22] (Fig. 93.4). The effect of  $1,25(\text{OH})_2\text{D}_3$  was dose dependent. In that study, topical treatment with an analog with very limited capacity to promote transcription,  $1\alpha,25$ -dihydroxylumisterol [150], also reduced UV-induced skin tumors, including SCC, though the lumisterol derivative was less effective than  $1,25(\text{OH})_2\text{D}_3$  [22]. As noted, VDR knockout mice are more susceptible to chemically or UV-induced skin tumor formation [129,130]. On the other hand,  $1\alpha$ -hydroxylase (*Cyp27b1*) knockout mice, which cannot make  $1,25(\text{OH})_2\text{D}_3$  or, presumably, other  $1\alpha$ -hydroxylated metabolites, are not more susceptible to chemically induced skin tumors [129,151] or, reportedly, to UV-induced skin tumors [109]. *Cyp27b1* knockout mice have normal hair but impaired barrier function and wound healing [19]. These observations raise the possibility that other naturally produced metabolites, including CYP11A1-derived metabolites of vitamin D, such as  $20(\text{OH})\text{D}_3$  [99], may have photoprotective effects [21,123]. Some published studies showing reductions in UV-induced CPD and oxidative DNA damage in skin cells and mice with  $20(\text{OH})\text{D}_3$  support this proposal [152,153]. CYP11A1 metabolites of over-irradiation products such as lumisterol have now been described [102]. These compounds, rather than being biologically “inert,” could also contribute to photoprotection [154]. There are other “vitamin D-like compounds” which, although not based on cholesterol, potentially bind to the alternative binding pocket on the

VDR. These include curcumin and its metabolites [150,155]. Curcumin is a well-known anticancer agent, in part due to its antioxidant properties at micromolar concentrations [156]. Oral or topical application of curcumin or its major metabolite at high doses has been reported to reduce UV-induced skin tumor formation [23,157].

#### 4. Mechanisms of protection from UV-induced skin tumors

There are several mechanisms whereby vitamin D compounds and the VDR might protect from UV-induced skin tumors. These include protection from UV-induced DNA damage and enhanced repair, via several pathways including reductions in reactive oxygen and nitrogen species, which would result in less oxidative and nitritative DNA damage as well as enhanced repair due to less damage of repair-associated proteins. Other mechanisms include increased energy availability, alterations in nuclear p53 protein, and phosphorylation and effects on PTEN and related proteins. Vitamin D compounds and the VDR also modify the Hh pathway and  $\beta$ -catenin, important in BCC [19,109] and reviewed in Chapter 25, and alter long-noncoding RNA (lncRNA) profiles, changing the balance between oncogenic and tumor suppressor lncRNAs [18] and reviewed in Chapter 25. Immune responses to UV are modified by  $1,25(\text{OH})_2\text{D}_3$  and other vitamin D compounds [20,22]. Once tumors have developed, the anti-proliferative and pro-differentiation

**FIGURE 93.4** Skin tumors in mice after chronic UV exposure. Skh:hr1 hairless (but immune competent) mice were exposed to  $0.66 \text{ kJ/m}^2$  UVB and  $20.30 \text{ kJ/m}^2$  UVA, approximately one minimal erythral dose of solar-simulated UV, on 5 days per week for 10 weeks. Immediately after each exposure, the dorsum of each mouse was painted with either vehicle (ethanol: propylene glycol: water 2:1:1 v/v) or  $11.4 \text{ pmol/cm}^2$  of  $1,25(\text{OH})_2\text{D}_3$  in vehicle. The mice were monitored for a further 30 weeks [22]. Skin tumors on the dorsal surface of 4 mice treated with vehicle (A) and 4 mice treated with  $1,25(\text{OH})_2\text{D}_3$  are shown.

actions of  $1,25(\text{OH})_2\text{D}_3$  and related compounds are likely to contribute to observed better outcomes in patients with higher circulating  $25(\text{OH})\text{D}$  [14,120].

#### 4.1 Reduction in DNA damage and enhancement of repair

Numerous studies have shown that vitamin D metabolites and CYP11A1 metabolites of lumisterol reduce UV-induced DNA damage [22,55,154,158,159]. The hormone  $1,25(\text{OH})_2\text{D}_3$  can reduce CPD in mouse models, in Skh:hr1 hairless mice [22,160], C57BL/6 [130], and BALB/c mice [99], as well as in human keratinocyte, melanocyte, and fibroblast cells [54,158–160], human ex vivo skin [161], and human in vivo skin [162]. This effect is concentration dependent [22,54] and can be observed from 0.5 h after UV, the earliest time point tested [54,55,161]. Reductions in UV-induced DNA damage by vitamin D compounds have been demonstrated by immunohistochemistry and image analysis [158,159,163] as well as by Comet assay for short DNA strands [154] or after T4 endonuclease 5 (T4N5) digestion (where T4N5 cuts DNA at sites of CPD) or after Ogg1 endonuclease (which cuts DNA at sites of oxidative damage) followed by alkaline gel electrophoresis [55]. In keratinocytes, melanocytes, and fibroblast cultures and in mouse and human skin,  $1,25(\text{OH})_2\text{D}_3$  also protects cells from apoptosis following UV irradiation [22,54,158,159,162,164], probably due to less DNA damage when compared with vehicle-treated cells [54]. This may be related to the ability of  $1,25(\text{OH})_2\text{D}_3$  to initiate cell cycle arrest and reduce growth to facilitate repair [164].

UV-irradiated human and mouse skin treated with  $1,25(\text{OH})_2\text{D}_3$  exhibited significantly reduced 8-oxoguanine and 8-nitroguanine, compared with vehicle-treated skin [55,161]. Time course studies with Comet assays incorporating digestion with the Ogg1 repair enzyme show treatment with physiological doses of  $1,25(\text{OH})_2\text{D}_3$  immediately after UV exposure significantly reduced Ogg1-sensitive sites in irradiated keratinocytes from 0.5 h onward [55]. This has been further corroborated by nuclear staining with a monoclonal antibody to 8-oxoguanine [161]. 6-4 photoproducts after UV are also reduced by  $1,25(\text{OH})_2\text{D}_3$  and CYP11A1 derivatives of lumisterol [154].

Although it has been reported that preincubation with  $1,25(\text{OH})_2\text{D}_3$  for at least 8 h prior to UV is required for reduction in CPD after UV in human keratinocytes [158], these protective effects of vitamin D compounds have been observed in vitro and in vivo whether the agents were given before UV [54,162], or applied immediately after exposure to UV [22,152,161,165].

UV-produced CPDs are not reduced at a normal rate in *Vdr* knockout mice [130,148] or in mouse explants

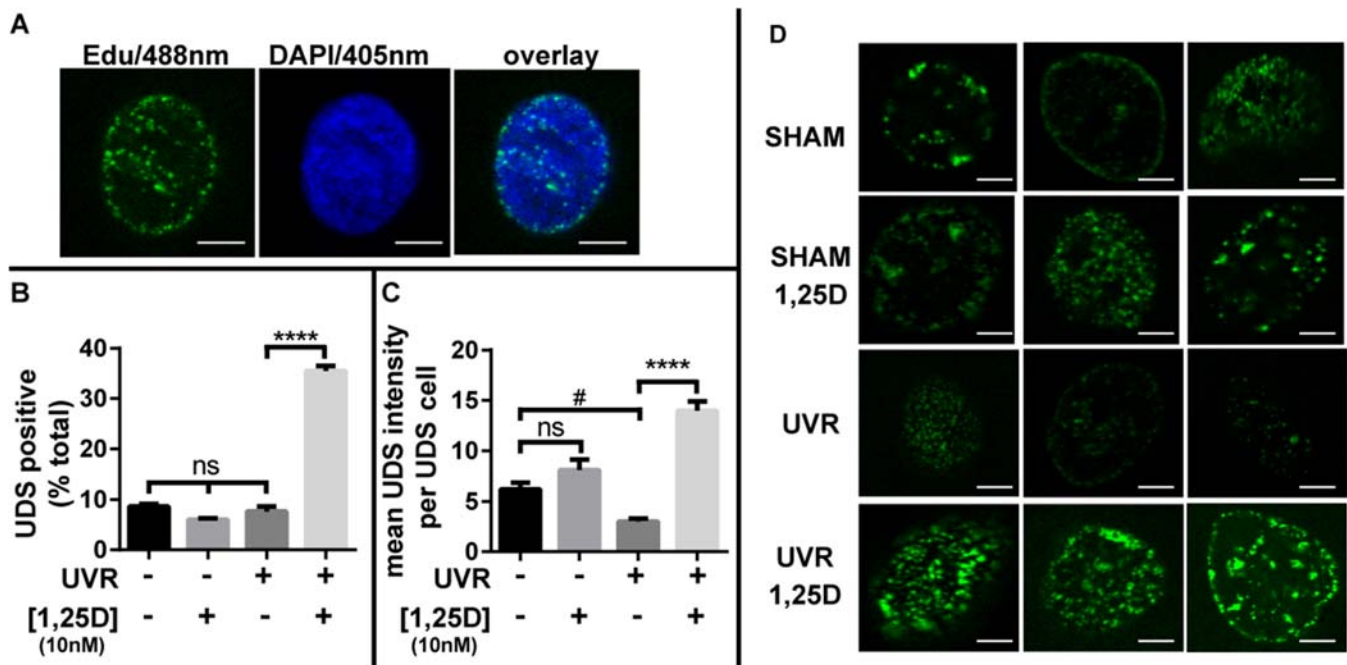

with reduced VDR [148] and neither CPD nor 8-oxoguanine was reduced in human keratinocytes in which either VDR or ERp57 had been knocked down [166]. As noted before, UV-generated CPD disappears at a much faster rate in a variety of model systems when  $1,25(\text{OH})_2\text{D}_3$  is provided [22,55,161]. These results may be reasonably interpreted to mean that DNA repair is reduced in *Vdr* knockdown conditions but enhanced by  $1,25(\text{OH})_2\text{D}_3$  and related compounds. There is now direct evidence of increased DNA repair in the presence of  $1,25(\text{OH})_2\text{D}_3$  demonstrated by increased unscheduled DNA synthesis in UV-exposed human keratinocytes (Fig. 93.5) [167].

#### 4.2 Role of VDR and other receptors

The VDR is clearly essential to the cancer prevention strategies of vitamin D steroids in skin. Zinser et al. first reported that VDR knockout mice were more susceptible to chemically induced skin tumors [129]. This was confirmed by Ellison et al. [130] who also reported that VDR knockout mice were far more susceptible to UV-induced skin tumors than wild-type mice. This has been confirmed by others [109].

As discussed in Chapters 10–13, most actions of the vitamin D hormone are mediated by the classical genomic pathway that results mainly in modulation of gene transcription [168]. There is reasonable evidence for the existence of an alternate, non-classical pathway that appears to be important for some actions of  $1,25(\text{OH})_2\text{D}_3$  [169,170], including photo-protection. This non-classical pathway is discussed in more detail in Chapter 22. The chemically synthesized, *cis*-locked  $1\alpha,25$ -dihydroxylumisterol<sub>3</sub> has little capacity to alter transcription of vitamin D target genes and so is considered an agonist of the non-classical pathway [150,171].  $1\alpha,25$ -dihydroxylumisterol<sub>3</sub> and other naturally occurring CYP11A1 lumisterol derivatives, which also have little trans-activating activity, reduced UV-generated CPD and other types of DNA damage to a similar extent as  $1,25(\text{OH})_2\text{D}_3$  in human primary melanocytes, fibroblasts, and keratinocytes [22,159,160,165].  $1\beta,25$ -Dihydroxyvitamin D<sub>3</sub> (HL) is an antagonist of the non-classical pathway [150], while (23S)-25-dehydro- $1\alpha$ -OH-D<sub>3</sub>-26,23-lactone (MK/TEI) is an antagonist of the classical vitamin D pathway [172]. Studies in all these cell types have clearly demonstrated that neither  $1\beta,25$ -dihydroxyvitamin D<sub>3</sub> (HL) nor (23S)-25-dehydro- $1\alpha$ -OH-D<sub>3</sub>-26,23-lactone (TEI) alters CPD after UV on their own. The classical antagonist, (23S)-25-dehydro- $1\alpha$ -OH-D<sub>3</sub>-26,23-lactone (TEI), had no effect on photo-protection by  $1,25(\text{OH})_2\text{D}_3$  in this system, but the presence of the non-classical antagonist  $1\beta,25$ -dihydroxyvitamin D<sub>3</sub> (HL) completely abolished the

**FIGURE 93.5** Unscheduled DNA synthesis was increased in primary human keratinocytes after treatment with  $1,25(\text{OH})_2\text{D}_3$  following UV irradiation. (A) Confocal microscopy image of the nucleus of an ssUV-irradiated keratinocyte scanned for thymidine analog (EDU) incorporation at 488 nm and counterstained with DAPI. This punctate staining of nuclear EDU was considered positive for unscheduled DNA synthesis (UDS). Scale bar represents 5  $\mu\text{m}$ . (B) Percentage of UDS-positive cells (as shown in A) as a proportion of total cells randomly counted by DAPI counterstain from keratinocytes 90 mins following UV irradiation (UVR), or nonirradiation, in response to 10 nM  $1,25(\text{OH})_2\text{D}_3$  or the vehicle treatment (-).  $n = 1000$  cells counted per treatment between triplicate experiments. (mean  $\pm$  SEM). Significantly different from all other treatment groups  $****P < .0001$ ; ns = no sig. diff. (C) Average intensity of EDU incorporation per UDS-positive cell, as measured by densitometry,  $n = 36$  UDS-positive cells quantified per treatment between triplicate experiments. (mean  $\pm$  SEM). Significantly different from UVR without  $1,25(\text{OH})_2\text{D}_3$   $****P < .001$ ; significantly different from vehicle treated nonirradiated  $\#P < .05$ . (D) Example images of cells used for the EDU intensity analysis shown in C (SHAM cells = nonirradiated, i.e., shielded from irradiation). Scale bar represents 5  $\mu\text{m}$ . Reproduced from Ref. [167] with permission.

reductions in CPD due to the presence of  $1,25(\text{OH})_2\text{D}_3$  [22,160,165].

As noted earlier, mice in which VDR has been deleted are more susceptible to UV-induced skin tumors [130]. VDR knockdown in human keratinocytes also abolished the reductions in CPD and 8-oxoguanine damage after UV with  $1,25(\text{OH})_2\text{D}_3$  as well as  $20(\text{OH})\text{D}_3$  and the lumisterol derivative,  $24(\text{OH})\text{L}_3$  [166]. The requirement for VDR was also examined in fibroblasts from patients with hereditary vitamin D-resistant rickets who have mutations in VDR [173]. Addition of  $1,25(\text{OH})_2\text{D}_3$  did not reduce CPD after UV in fibroblasts from a patient with a mutation resulting in an early stop codon in the VDR gene (R50X), which expressed no detectable VDR (VDR null fibroblasts) [173,174]. On the other hand, fibroblasts from a patient with a missense mutation in the region coding for the DNA-binding domain (V26M) [175] (DBD-mutant fibroblasts) still showed significant reductions in UV-induced CPD after addition of  $1,25(\text{OH})_2\text{D}_3$  or the cis-locked compound,  $1\alpha,25$ -dihydroxylumisterol $_3$ . This indicates that at least reductions in post-UV CPD could be mediated by a VDR with little ability to bind to DNA or to induce genomic

transactivation. Further studies with fibroblasts from a patient with a 5-base-pair deletion/8-base-pair insertion in Helix 1 of the VDR ligand-binding domain (LBD), which abolished classical ligand binding [176], still allowed  $1,25(\text{OH})_2\text{D}_3$  or  $1\alpha,25$ -dihydroxylumisterol $_3$  to reduce post-UV CPD [173]. The interpretation of these results is that a VDR is needed for reductions in UV-induced CPD by vitamin D compounds, but that receptor needs not be able to bind to DNA or exhibit classical binding to  $1,25(\text{OH})_2\text{D}_3$ .

What about ERp57/PDIA3/MARRS, which has been proposed to be the main binding protein for  $1,25(\text{OH})_2\text{D}_3$  and related compounds for nonclassical responses [177] or at least a critical element in mediating responses such as rapid induction of intestinal calcium transport [170,178]? When ERp57 was knocked down in normal human fibroblasts or keratinocytes by siRNA,  $1,25(\text{OH})_2\text{D}_3$  failed to reduce post-UV CPD [173]. Likewise, the use of a neutralizing antibody to ERp57 (Ab 099, a rabbit polyclonal antibody that recognizes the N-terminal of ERp57 [177] and that could only access a cell membrane associated protein) abolished the protective effect of  $1,25(\text{OH})_2\text{D}_3$  in skin fibroblasts [173]. In this

context, it is worth noting that the classical VDR has been found to be present on the cell membrane in association with caveolae [179]. Furthermore, in normal skin fibroblasts, VDR and ERp57 were coimmunoprecipitated in nonnuclear cellular lysates [173]. Similarly, protective effects of  $1,25(\text{OH})_2\text{D}_3$  and CYP11A1 derivatives of vitamin  $\text{D}_3$ , such as  $20(\text{OH})\text{D}_3$  or of lumisterol, such as  $24(\text{OH})\text{L}_3$ , against both CPD and oxidative DNA damage, were abolished in normal human keratinocytes when either the VDR or ERp57 was knocked down by siRNA [166].

As noted in Chapter 22, in chondrocytes and other cell types, the effects of  $1,25(\text{OH})_2\text{D}_3$  and other agents such as  $1\alpha,25$ -dihydroxylumisterol $_3$  and  $25(\text{OH})\text{D}_3$  on ion channel currents via nonclassical pathways involve the opening of chloride channels [150,171,180]. Chloride channel opening is inhibited by 4,4-diisothiocyanatostilbene-2,2-disulfonic acid (DIDS), and in the presence of DIDS, this nonclassical pathway is blocked [150,171,180]. In human keratinocytes, DIDS had no effect on its own, but in its presence, there was no reduction in CPD after UV with  $1,25(\text{OH})_2\text{D}_3$  [181].

Not all actions of  $1,25(\text{OH})_2\text{D}_3$  or related compounds in skin cells that are potentially useful in photoprotection require the VDR. These actions include the increase in overall p53 expression [173], inhibition of Smoothed, part of the Hh pathway [110,182]. Not all actions are inhibited by DIDS, such as reductions in post-UV nitrotyrosine [181]. Nevertheless, overall, the data are consistent with the hypothesis that, at least in part, vitamin D compounds bind to the alternative pocket on the VDR at the cell membrane, which in turn, through an action that involves the protein ERp57 at the cell membrane, results in opening of chloride channels, and this leads to several functional changes in UV-irradiated cells, which facilitate reductions in CPD.

DNA repair involves substantial chromatin remodeling [57], and  $1,25(\text{OH})_2\text{D}_3$  regulates epigenetic mechanisms that maintain the transcription of its target genes that contribute to its regulatory network [183,184]. Though direct interaction of the liganded VDR with chromatin remodeling proteins has been recently described [185], much VDR-mediated chromatin remodeling occurs via classic genomic pathways. For example, the VDR/RXR dimer recruits histone acetyltransferases (HATs) such as p300/CBP and steroid receptor coactivators 1 and 2 (SRC-1 and SRC-2), which carry out the acetylation reactions that open up the chromatin structure to facilitate transcription [168]. Other photoprotective mechanisms, such as suppression of Hh pathway signaling, and induction of metallothionein and XPC mRNA, appear to be via classic genomic alterations in gene transcription [186]. It has been proposed

that some actions of vitamin D- or lumisterol-derived compounds may be mediated by retinoic acid orphan receptors ROR $\alpha$  and  $\gamma$  or the aryl hydrocarbon receptor since some of these compounds such as  $20\text{S}(\text{OH})\text{D}_3$  and  $20,23(\text{OH})_2\text{D}_3$  have been shown to act via these receptors [154].

As indicated before, agents such as  $1\alpha,25$ -dihydroxylumisterol $_3$  and  $20(\text{OH})\text{D}_3$ , which have been characterized as agonists of the nonclassical pathway with little transactivating activity, also reduce DNA damage and UV-induced immune suppression in mice [22,152]. Since DNA damage and immune suppression both contribute to photo-carcinogenesis, it is likely that nonclassical pathways play an important role in protection from UV-induced tumors. It should be noted, however, that although  $1\alpha,25$ -dihydroxylumisterol $_3$  appeared equivalent to  $1,25(\text{OH})_2\text{D}_3$  in reducing both UV-induced DNA damage and immune suppression in mice, it was less effective than  $1,25(\text{OH})_2\text{D}_3$  in reducing UV-induced skin tumors or SCC in these animals [22], suggesting that at least some of the photoprotective effects of  $1,25(\text{OH})_2\text{D}_3$  are due to genomic mechanisms. Another low calcemic vitamin D analog, which has some transactivating capacity, 1-hydroxymethyl-16-ene-24,24-difluoro-25-hydroxy-26,27-bis-homovitamin  $\text{D}_3$ , QW-1624F2-2 (QW), which has little calcemic effect [187], reduced levels of UV-induced CPD in primary human keratinocytes, dermal fibroblasts [188], melanocytes, and in mouse skin in vivo [160] as well as inhibiting UV-induced immune suppression [160,188]. In these studies, its photoprotective effectiveness was equivalent to that of  $1,25(\text{OH})_2\text{D}_3$  [160]. QW reduced acute UV-induced DNA and immune system damage and at a dose 10-fold that used in UV studies reduced skin tumors in a model of chemical-induced skin carcinogenesis [189]. At the single dose tested in a chronic UV protocol, however, QW was not effective to reduce UV-induced skin carcinogenesis [188]. A similar failure to reduce UV-induced photo-carcinogenesis also was reported for some other vitamin D-derived and lumisterol-derived agents [23,24,26]. In contrast, the vitamin D-like agent curcumin reduced UV-induced tumors whether given orally or topically [157], and its major metabolite, tetrahydrocurcumin, effectively reduced UV-induced tumors after topical application [23]. While there may be other markers of efficacy to reduce UV-induced skin tumors (see "other potential contributors to photo-carcinogenesis" in the following), constraints of photo-carcinogenesis studies include the length of the studies (40 weeks) and the large number of mice needed per treatment group ( $n = 20$ ), which make them labor-intensive and expensive, thus limiting the number of treatment doses that can be tested in a single study.

### 4.3 Reduced generation of reactive oxygen and nitrogen species

During normal cellular metabolism, the continually generated low levels of ROS play a role in many normal cellular processes including growth control and differentiation [190]. In addition, activation of photoreceptors in skin by UV absorption generates free radicals by electron transfer or hydrogen abstraction processes in other molecules, or by energy transfer to molecular oxygen increasing the rate of ROS production [191]. Redox balance is regulated by intrinsic cellular antioxidant systems, which consist of both antioxidant enzymes and non-enzymatic antioxidants [192]. For example, superoxide anions are converted by superoxide dismutase to hydrogen peroxide, which is converted to water and oxygen by catalase. Insufficient enzyme activity increases the levels of superoxide and hydrogen peroxide that form highly toxic peroxynitrite and hydroxyl ions, respectively. Non-enzymatic free radical scavenging antioxidants, glutathione, metallothionein, thioredoxin, vitamins C and E, and carotenoids are also present in skin, but may be inactivated by UV-induced ROS and RNS. Glutathione peroxidase, superoxide dismutase, and catalase expression are downregulated for several days following UV exposure, which would permit an exponential increase in ROS and RNS [193]. Inflammatory cells induced by UV also migrate into irradiated skin and may contribute to increased levels of ROS [88].

UV-induced ROS can overcome the intrinsic enzymatic and non-enzymatic antioxidant systems within the skin, causing an imbalance between ROS and antioxidant systems. Loss of cellular redox homeostasis from UV has been implicated in both photo-carcinogenesis and photo-aging. The resulting oxidative stress would perturb cellular defenses against DNA damage, oxidative and nitrative modifications to proteins, and lipid peroxidation of membranes, leading to cell death.

UV radiation is a very potent oxidative stressor leading to significant alterations in the activity of the nuclear factor-erythroid-2-related factor 2 (Nrf2). The activity of the redox-sensitive transcription factor Nrf2 is regulated by a number of mechanisms, which determine its nuclear import/export balance and its degradation [194]. Nrf2 activates genes that encode antioxidant enzymes such as catalase, superoxide dismutase, and others [195]. In the absence of oxidative stress, Nrf2 binds to Kelch-like ECH-associated protein (Keap 1). Keap 1 links Nrf2 to the cytoskeleton to retain Nrf2 in the cytoplasm, thereby promoting its degradation [194]. On the other hand, oxidative stress enables Nrf2 to escape Keap1-mediated proteasomal degradation, leading subsequently to Nrf2 stabilization and its translocation into the nucleus [194]. There is evidence that 1,25(OH)<sub>2</sub>D<sub>3</sub> activates the Nrf2–Keap1 antioxidant pathway which

ameliorates oxidant stress [196–198] including in UV-exposed keratinocytes [154] and thus potentially, oxidative DNA damage.

Treatment of keratinocytes with 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited the activation of stress-activated protein kinases, such as c-Jun N-terminal kinase (JNK), [199] and inhibited apoptosis induced by oxidative stress, TNF $\alpha$  and hydrogen peroxide cytotoxicity [200–202], possibly by increasing inherent antioxidant systems [154]. Overproduction of NO can alter the mitochondrial membrane potential. This can allow the release of pro-apoptotic proteins, activating the mitochondrial apoptotic pathway [203]. There is some evidence that the VDR acts as a gatekeeper of mitochondrial respiratory chain activity. In immortalized keratinocytes, HaCaT cells, VDR silencing increased transcription of the subunits II and IV of cytochrome c oxidase and was accompanied by sharp increases in the mitochondrial membrane potential, which sensitized the cells to oxidative stress [204]. There is also some evidence that mitochondrial damage after UV is repaired more quickly in the presence of 1,25(OH)<sub>2</sub>D<sub>3</sub> [167]. Consistent with UV-induced mitochondrial damage [205], the mitochondrial protein PINK1 was increased in human keratinocytes after a dose of UV that was not high enough to increase caspase activity [167]. This was accompanied by an increase in ROS [167]. In this study [167], when 1,25(OH)<sub>2</sub>D<sub>3</sub> was added to keratinocyte cultures immediately after UV exposure, there was evidence of enhanced mitochondrial-derived vesicle-dependent mitophagy and suppression of mitochondrial membrane potential, both associated with decreased ROS [206,207].

Metallothionein is a cysteine-rich protein, which functions in metal detoxification and is a potent oxygen radical scavenger. When metallothionein was upregulated by cadmium in UV-irradiated mouse skin, the result was reduced UV-induced apoptotic sunburn cells and reduced photodamage [208]. Superoxide and hydroxyl radicals were also reduced. Induction of metallothionein by 1,25(OH)<sub>2</sub>D<sub>3</sub> was first observed in mouse keratinocytes in vitro as well as mouse liver, kidney, and skin in vivo by Karasawa and colleagues [209]. Further studies demonstrated an inhibition of UV-induced keratinocyte death in vitro and a reduction in sunburn cells in vivo in mouse skin following 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment, with a concurrent increase in metallothionein levels, though independently of glutathione [163,210]. There is also a report that 1,25(OH)<sub>2</sub>D<sub>3</sub> increased glutathione and reduced ROS in monocytes through upregulated glutathione glutamate cysteine ligase and glutathione reductase, which catalyze glutathione biosynthesis [211]. There is evidence that 1,25(OH)<sub>2</sub>D<sub>3</sub> and analogs can directly induce antioxidant genes, for example, glucose-6-phosphate

dehydrogenase, glutathione peroxidase, and thioredoxin reductase [212]. It was shown that  $1,25(\text{OH})_2\text{D}_3$  protected against hydrogen peroxide-induced cell death in prostate epithelial cell lines through transcriptional activation of glucose-6-phosphate dehydrogenase, followed by an increase in glutathione levels [212]. A protective effect of  $1,25(\text{OH})_2\text{D}_3$  in keratinocytes against not only UV but also treatment with  $\text{TNF}\alpha$  or ceramides has been reported. This appeared to be mediated by production of sphingosine-1 phosphate, which prevented apoptosis [213]. Relatively high doses of  $1,25(\text{OH})_2\text{D}_3$  (approximately  $10^{-7}$  M), however, were required to provide protection in this study [213].

Vitamin D compounds are not antioxidants, and there is even evidence that  $1,25(\text{OH})_2\text{D}_3$  increases reactive oxygen species in adipose tissue [214]. In skin, however, there is ample evidence that  $1,25(\text{OH})_2\text{D}_3$  and related compounds reduce both reactive oxygen and nitrogen species after UV [22,54,154,167]. The decrease in nitrite in keratinocyte cultures with  $1,25(\text{OH})_2\text{D}_3$  was similar to that seen with nitric oxide synthase inhibitors, aminoguanidine and L-N-monomethylarginine [54]. Comparable reductions were also shown by whole-cell ELISA specific to detect 3-nitrotyrosine [22,181]. As noted earlier, the mechanisms for reductions in ROS and RNS appear to include increased Nrf2 as well as its targets heme oxygenase-1, catalase, and superoxide dismutase/Mn [154] together with enhanced repair of mitochondrial damage [167].

Reduction in reactive oxygen or nitrogen species generated would directly reduce the number of oxidized or nitrated guanine bases, as reported [55,161]. Reduced nitric oxide intermediates would also facilitate DNA repair, since there is evidence that nitric oxide and its intermediates inhibit repair of CPD by nitrosylation of DNA repair proteins and preferential inhibition of excision and ligation steps of nucleotide excision repair [62,215]. Furthermore, peroxynitrite, produced as a result of a chemical reaction between nitric oxide and superoxide, has been reported to inactivate Ogg1, a key base excision repair enzyme, critical for repairing both 8-oxoguanine and 8-nitroguanine [61]. These results are consistent with the proposal that the action of  $1,25(\text{OH})_2\text{D}_3$  to reduce DNA damage after UV irradiation may be partly due to a decrease in ROS and RNS, which leads to reduced oxidative and nitrative DNA damage as well as increased repair of all types of DNA damage [22,54,216].

#### 4.4 Role of tumor suppressor protein p53

DNA damage, such as after UV exposure, activates the tumor suppressor p53, a 53 kDa protein involved

in regulation of the cell cycle and facilitation of DNA repair [38,217]. After DNA damage, p53 is modified by phosphorylation and acetylation of at least 20 sites through different stress signaling pathways, leading to accumulation of p53 in the nucleus [217]. Under normal physiological conditions, p53 is present in cells at very low levels due to its very short half-life of less than 30 min [218,219]. In normal cells, p53 is bound to its negative regulator, the MDM2 protein. MDM2 maintains p53 at low levels by increasing its susceptibility to proteolysis by the 26S proteasome. The MDM2 gene is a proto-oncogene, which functions mainly to modulate the activity of p53 [219]. Modifications in p53 enhance its accumulation mostly by inhibiting degradation facilitated by MDM2. These processes lead to nuclear accumulation of p53 that reaches maximum levels 12 h after UV radiation [218]. While phosphorylation of p53 at Ser<sup>46</sup> is important for apoptosis control [220], phosphorylation at Ser<sup>15</sup> may be important for accumulation of p53 in the nucleus and for transactivation of downstream genes to induce cell cycle arrest in the G1 phase, and other actions that facilitate DNA repair [221]. If the DNA damage is too severe to be repaired, apoptotic pathways are activated to eliminate the damaged cell before it replicates. p53 can upregulate the expression of pro-apoptotic genes such as Bax and Fas/Apo-1, or can downregulate expression of anti-apoptotic genes such as Bcl-2 [43]. In addition to disrupting the cell cycle to allow time for DNA repair, p53 directly affects the transcription of genes that control NER [222,223] and base excision repair [66] pathways, as well as pro- or anti-apoptotic pathways [43]. p53 mediates the transcription of GADD45, which assists DNA repair by binding to DNA, increasing its accessibility to repair enzymes [224].

The p53 tumor suppressor gene is one of the most commonly mutated genes in UV-induced skin cancers [43,225]. Physiological doses of UVA and UVB can induce inactivating mutations in p53. Mutations in the tumor suppressor p53 in engineered human skin were found to be predominantly UVA finger print mutations induced by oxidative damage located in the basal layer of the epidermis [38]. Under circumstances where there are mutations in p53, reduced global genome repair of CPD is observed, but transcription-coupled repair continues [226]. A positive association between mutations in the tumor suppressor p53 gene in UV damaged skin in mouse and human skin before skin tumors appear provides evidence for their involvement in skin carcinogenesis [38]. DNA repair was blocked in cells transfected with a dominant-negative p53 [227], and early-onset tumor formation increased in homozygous p53 knockout mice [228]. The gene for the DNA strand sensor protein kinase (ATM) acts by phosphorylating p53 at serine 15 and is inactivated in patients with the genetic disorder ataxia telangiectasia. In this disease,

patients suffer from genome instability and cancer [229]. Several p53 phosphorylation sites are commonly inactivated as a result of UV-induced DNA damage. When such mutations are engineered in mice, they promote photo-carcinogenesis [230].

Increased nuclear p53 protein expression, beyond the increase with UV alone, has been reported by 3 h post-exposure in human keratinocytes and melanocytes treated with 1,25(OH)<sub>2</sub>D<sub>3</sub> [54,160], though not in all studies [153]. Increased phosphorylation of p53 at Ser<sup>15</sup> occurs after UV [167], with nuclear accumulation of p53-Ser<sup>15</sup> [154]. While addition of CYP11A1 derivatives of vitamin D<sub>3</sub> or lumisterol leads to further increases in nuclear accumulation of p53-Ser<sup>15</sup> [154], treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> itself does not further increase p53-Ser<sup>15</sup> [167] or its nuclear accumulation [154]. In human skin fibroblasts that did not express the VDR, 1,25(OH)<sub>2</sub>D<sub>3</sub> treatment increased total cellular p53 expression, but did not protect against UV-induced CPD [173]. Thus, while further upregulation of p53 by 1,25(OH)<sub>2</sub>D<sub>3</sub> after UV, possibly by a VDR independent process [130,173], would be likely to contribute to enhanced DNA repair, the role that this process plays in reducing post-UV DNA damage in the presence of vitamin D compounds is currently unclear.

#### 4.5 DNA repair proteins and processes

There is some evidence that 1,25(OH)<sub>2</sub>D<sub>3</sub> may enhance expression of proteins involved in DNA damage recognition or repair. Moll et al., using array technology, reported that treatment of human keratinocytes in culture with 1,25(OH)<sub>2</sub>D<sub>3</sub> upregulated mRNA for the CPD damage recognition proteins DDB2 (part of the XPE complex) and XPC [231]. Song reported significantly increased expression of DDB2 and XPC protein in biopsies of human subjects exposed to UV and treated topically with 1,25(OH)<sub>2</sub>D<sub>3</sub> or a vitamin D-like compound [216], which was confirmed in human skin explants [232]. It is possible that this 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced increase in XPC is a consequence of p53 upregulation [233]. Evidence of the importance of this upregulation of XPC by 1,25(OH)<sub>2</sub>D<sub>3</sub> after UV is that knockdown of XPC in human keratinocytes with siRNA to XPC, compared with control siRNA, abolished the reduction in CPD in the presence of 1,25(OH)<sub>2</sub>D<sub>3</sub> [234].

There may also be important effects of VDR on epigenetic actions of DNA damage recognition proteins. There is evidence that in keratinocytes from VDR knockout mice, the key DNA repair protein XPC accumulated normally at sites of DNA damage but dissociated far more slowly compared with control keratinocytes [32]. The slower dissociation of XPC led to decreased binding of XPF endonuclease, which

reduced the rate of removal of DNA damage in the form of pyrimidine–pyrimidone (6–4) photoproducts in VDR-depleted skin cells [32].

The mechanism of increased XPC expression after UV and 1,25(OH)<sub>2</sub>D<sub>3</sub> may involve phosphatase and tensin homolog deleted on chromosome 10 (PTEN). PTEN is a negative regulator of the oncogenic acutely transforming retrovirus AKT8 in rodent T cell lymphoma (AKT) pathway and acts as a tumor suppressor. PTEN is defective in a number of different cancers, including glial, prostate, breast, lung, endometrial cancers, and melanoma [235]. Susceptibility to tumor induction was increased in mice with PTEN deletion, and PTEN levels were lower in SCC and papillomas compared with normal skin in a mouse model of UV-induced skin carcinogenesis [236]. Furthermore, PTEN levels were reduced in SCC and actinic keratoses from human subjects compared with normal skin [237]. Activation of the AKT pathway allows for evasion of cell death pathways, providing favorable conditions for cancer progression. AKT pathway activation commences with the phosphoinositide 3-kinase (PI3K)-induced conversion of phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>) to phosphatidylinositol-3,4,5-trisphosphate (PIP<sub>3</sub>) [238]. Conversely, PTEN inhibits PI3K-dependent signaling by dephosphorylating PIP<sub>3</sub> to PIP<sub>2</sub>. PTEN thus decreases levels of activated AKT and enables effective cell cycle regulation.

Studies by Ming and colleagues showed that UVB downregulates PTEN in the immortalized keratinocyte line, HaCaT, as well as in primary human keratinocytes and in mouse skin in an AKT and extracellular signal-regulated kinase (ERK)<sub>1/2</sub>-dependent manner [237]. Further studies by this group showed that PTEN downregulation impairs global genomic NER, which is necessary for removal of UV-induced DNA lesions including CPD. Specifically, loss of PTEN resulted in suppression of a key player in the global genomic NER process, the xeroderma pigmentosum group C protein (XPC), which contributes to global genomic NER by way of DNA damage recognition. This was shown to be mediated through AKT and p38 signaling [239]. Studies by Shariev et al. demonstrated that solar-simulated UV decreased PTEN levels in primary human melanocytes and in Skh:hr1 hairless mouse skin, as well as in human melanoma cells [240]. Addition of 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited this UV-induced depletion of PTEN [240] likely in part due to suppression of AKT phosphorylation after UV [167]. Taken together with the study noted before by Song et al. showing 1,25(OH)<sub>2</sub>D<sub>3</sub> increased XPC protein expression in biopsies of UV-exposed human skin [216], PTEN is a likely target for 1,25(OH)<sub>2</sub>D<sub>3</sub> in its protective effect against UV-induced DNA lesions. Indeed, it has been suggested that the VDR can bind the PTEN promoter in gastric cancer cells to inhibit apoptosis [241].

PTEN may also be important at later stages of carcinogenesis in that PTEN contributes to melanoma development [242] and  $1,25(\text{OH})_2\text{D}_3$  has been shown to reduce melanoma cell viability in a PTEN-dependent process [243].

DNA repair is a process requiring *energy*, but energy generation by skin cells is greatly reduced after UV exposure through several mechanisms [244,245]. There is decreased ATP production from oxidative phosphorylation due to damage to mitochondria [246]. UV irradiation of keratinocytes increases poly(ADP-ribose) polymerases (PARPs), principally PARP-1, which also results in energy depletion [245].

As noted before, addition of  $1,25(\text{OH})_2\text{D}_3$  to UV-exposed keratinocytes enhances the mitochondrial repair process of mitophagy. This reduces ROS but does not increase oxidative phosphorylation measured by oxygen consumption rates on SeaHorse analysis [166,167]. Furthermore, use of the oxidative phosphorylation inhibitor oligomycin does not alter CPD reductions in the presence of  $1,25(\text{OH})_2\text{D}_3$  [166,167].

In contrast, the glycolysis inhibitor, 2-deoxyglucose, when added to UV-irradiated keratinocytes, completely blocks the reduction in CPD in the presence of  $1,25(\text{OH})_2\text{D}_3$ , indicating that glycolysis is the major source of energy for DNA repair after UV [167]. This increased glycolysis is likely to involve suppression of PARP-1 activity. After UV radiation, formation of DNA strand breaks activates pathways that consume nicotinamide adenine dinucleotides (NAD). PARPs are principal agents in this process, which function to transform NAD into polymers of ADP-ribose and thus modify proteins post-translation [247]. PARP-1, the oldest member of the PARP family, is induced by UV irradiation and is typically involved in DNA repair and cell death and has been shown to modulate chromatin remodeling, an essential step in DNA repair [248].

As noted before, exposure to UV results in induction of PARP-1, which is directly activated upon recognition and binding to damaged DNA [245]. It has previously been thought that PARP-1-induced cell death arose from energy depletion mainly due to excessive use of NAD<sup>+</sup> within the cell [245]. Certainly, replacement with oral nicotinamide has been shown to reduce new non-melanoma skin cancers and actinic keratoses in human subject over 12 months in a phase III clinical trial [249]. Perhaps more importantly, PARP-I inhibits hexokinase, the rate-limiting enzyme in glycolysis [250,251]. It seems that  $1,25(\text{OH})_2\text{D}_3$  is able to suppress PARP-1 activity in immortalized keratinocytes [252] and normal human keratinocytes [26], which would alleviate the blockade of glycolysis. UV stimulates phosphorylation of ERK<sub>1/2</sub> [239]. Increased ERK<sub>1/2</sub> phosphorylation has been linked to PARP-1 activation [253], and  $1,25(\text{OH})_2\text{D}_3$  inhibits UV-induced ERK<sub>1/2</sub>

phosphorylation, a potential explanation for suppression of PARP-1 [167].

As well as increased ERK<sub>1/2</sub> phosphorylation, UV exposure stimulates phosphorylation of AKT [239]. These, in turn, activate mammalian target of rapamycin complex 1 (mTORC1) to promote growth and inhibit autophagy [19,167,254]. It should be noted that alterations in phosphokinase signaling by  $1,25(\text{OH})_2\text{D}_3$  after exposure to UV are dual in nature. While phosphorylation of AKT, ERK, mTOR, and others that support energy-costly growth pathways were suppressed with  $1,25(\text{OH})_2\text{D}_3$ , pathways that are important for DNA repair and cell survival, such as phosphorylation of p53, stress-activated protein kinase/cJun N-terminal kinase, or UV resistance-associated gene (UVRAG), were maintained at the increased levels seen after UV exposure [167].

One pathway for energy conservation is autophagy [255], a process that is reportedly enhanced by  $1,25(\text{OH})_2\text{D}_3$  in monocytes/macrophages as well as breast cancer cells [256–258] and probably in keratinocytes [259]. Treatment of keratinocytes with  $1,25(\text{OH})_2\text{D}_3$  immediately after solar-simulated UV (ssUV) irradiation increased autophagy through alterations in several signaling pathways including suppressed phosphorylation of ERK<sub>1/2</sub>-Thr<sup>202</sup>Y<sup>204</sup>, AKT-Ser<sup>473</sup>, and mTOR Ser<sup>2448</sup> acting through glycogen synthase kinase-3 (GSK<sub>3</sub>) [167]. Although increased autophagy was not essential for the observed increases in repair of DNA damage [167], changes in these signaling pathways have many functional effects contributing to enhanced DNA repair [19,167].

#### 4.6 Vitamin D compounds and UV-induced immune suppression

As noted before, UV radiation is an important environmental immune suppressant in humans [88] and that suppression is key to skin tumor development [260,261]. Topical application of  $1,25(\text{OH})_2\text{D}_3$  to non-UV-exposed human skin has been found to induce immune suppression at a similar level to that resulting from UV irradiation only [162]. Application of the  $1,25(\text{OH})_2\text{D}_3$  analog, calcipotriol, also caused immune suppression in people and mice [262,263] but also suppressed polymorphic light eruptions, also known as “sun allergy” [264,265].

In other studies in mice, topical application of  $1,25(\text{OH})_2\text{D}_3$  and related compounds, reduced UV-induced systemic immunosuppression [22,23,26,152,266]. The vitamin D-induced protection against photo-immune suppression has been shown to display a gender bias, with greater protective effects observed in female compared with male mice [266]. Male mice and human males are

more susceptible to UV-induced immune suppression [90,91]. Male mice are more immune suppressed by topical  $1,25(\text{OH})_2\text{D}_3$  at lower doses than female mice [266]. Reduced susceptibility of female mice to immune suppression may indicate a link between female sex hormones/receptors and  $1,25(\text{OH})_2\text{D}_3$  actions.  $1,25(\text{OH})_2\text{D}_3$  has been reported to modulate estrogen receptor expression [267,268]. The estrogen receptor  $\beta$  is the only estrogen receptor in mouse skin [269]. In female transgenic mice that did not express estrogen receptor  $\beta$ , protection by  $1,25(\text{OH})_2\text{D}_3$  against photo-immune suppression was not demonstrated [266]. Use of an estrogen receptor  $\beta$  antagonist had a similar effect [266], suggesting that the presence of a functional estrogen receptor  $\beta$  in skin contributes to reduced UV immunosuppression and to detection of a protective effect by  $1,25(\text{OH})_2\text{D}_3$ .

The protection by  $1,25(\text{OH})_2\text{D}_3$  from photo-immune suppression whether assessed by contact hypersensitivity response or by delayed-type hypersensitivity response has also been observed in C3H and C57Bl/6 female mice [270]. In a study by a different group, vitamin D-replete status protected C57Bl/6 mice from UV-induced immune suppression, as well as DNA damage, but was not effective in BALB/c mice [271]. It is not yet clear why the use of different model systems produces different results, although, apart from sex and species differences, different UV sources, differences in the doses of UV and the spectrum delivered and different doses of topical  $1,25(\text{OH})_2\text{D}_3$  may contribute.

Another proposed mechanism for the observed  $1,25(\text{OH})_2\text{D}_3$ -mediated reduction of post-UV immune suppression in some models is a reduction in the expression of the inflammatory cytokine, IL-6 [79,199], which is itself a potent inducer of IL-10, an endogenous immunosuppressant [78]. Furthermore, as noted earlier, metallothionein mRNA expression is induced by  $1,25(\text{OH})_2\text{D}_3$  in cultured epidermal keratinocytes [209]. Since UV-induced immune suppression was increased in metallothionein knockout transgenic mice [272,273], this mechanism might be responsible, at least in part, for the reduction in photo-immune suppression by  $1,25(\text{OH})_2\text{D}_3$ .

UV exposure increases pro-inflammatory cytokines such as IL-6 and tumor necrosis factor  $\alpha$  probably via activation of the nuclear factor kappa B (NF- $\kappa$ B) signaling pathway [274].  $1,25(\text{OH})_2\text{D}_3$  and CYP11A1 derivatives of vitamin  $\text{D}_3$  and lumisterol have been reported to decrease NF- $\kappa$ B activation and inflammatory cytokines in keratinocytes after UV exposure [79,154,199]. Not surprisingly, given these results, it has been consistently reported that topical treatment with  $1,25(\text{OH})_2\text{D}_3$ ,  $20(\text{OH})\text{D}_3$ ,  $1,25$ -dihydroxylumisterol $_3$ , and a CYP11A1 derivative of lumisterol,  $24(\text{OH})\text{L}_3$ , reduces UV-induced skin edema in mice [22,26,152]. There is evidence of an inverse linear relationship between serum  $25(\text{OH})\text{D}$  and inflammatory markers

such as C-reactive protein, at least below  $50 \text{ nmol/L}$  [275]. This suppression of inflammation by good vitamin D status has been postulated to partly explain the better prognosis for patients with melanoma who have higher  $25(\text{OH})\text{D}$  at baseline [120]. This reduction in local and systemic inflammation may contribute to reduced progression of skin cancers and/or melanoma [120].

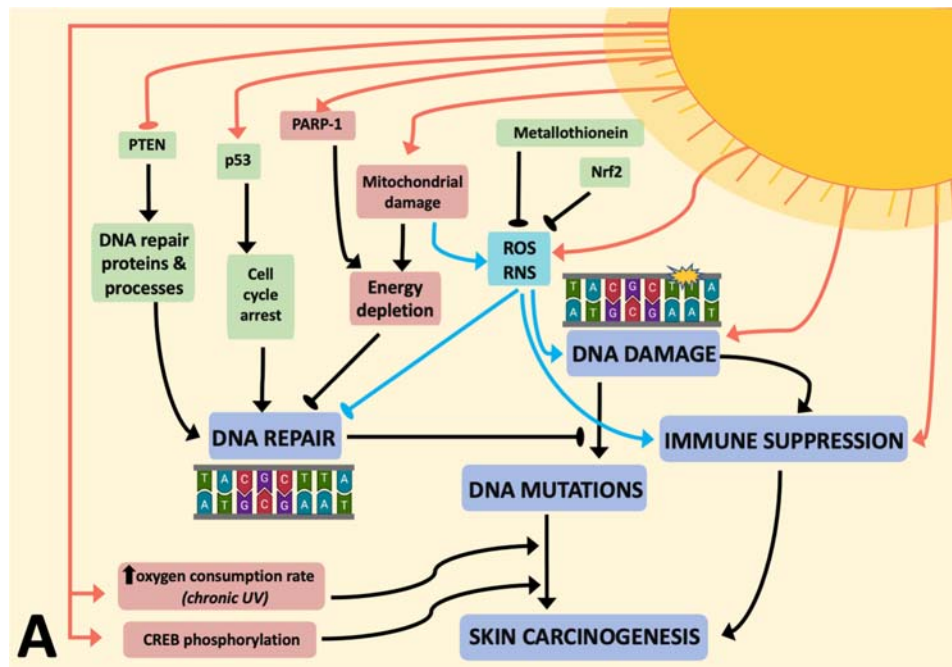

#### 4.7 Other potential contributors to reduced photo-carcinogenesis

Changes in energy metabolism are critical for neoplastic change and survival [276]. In particular, using the Skh:hr1 (hairless) mouse model of photo-carcinogenesis, these authors showed that the development of SCC-type skin tumors in these mice after chronic UV exposure was dependent on the upregulation of the distal part of the electron transport chain in the later stages of oxidative phosphorylation [276]. This was reflected in an increased oxygen consumption rate in keratinocytes derived from mouse skin after exposure to chronic UV [276]. This activation of the later stages of the electron transport chain was essential for synthesis of ATP and, importantly, pyrimidine nucleotides [276]. As noted earlier, single-dose UV acutely inhibited both glycolysis and oxidative phosphorylation [167]. While  $1,25(\text{OH})_2\text{D}_3$  increased glycolysis after a single dose of UVR, which was important for increased DNA repair at this time,  $1,25(\text{OH})_2\text{D}_3$  reduced oxygen consumption rate after UV and under basal conditions [166]. Given reports that other agents that reduce oxygen consumption rates such as leflunomide and metformin reduce pre-malignant and SCC-type tumors in mice after UV [276,277], it is not unreasonable to propose that this suppression of oxidative phosphorylation by  $1,25(\text{OH})_2\text{D}_3$  plays a role in reduction in skin tumors after chronic UV exposure.

A further UV-induced change in keratinocyte function is increased phosphorylation of cyclic AMP response-binding element protein (CREB) at Serine<sup>133</sup> at least in part as a result of UV stimulation of ERK $_{1/2}$  phosphorylation [166,278]. Inhibition of CREB phosphorylation by the plant-derived kaempferol in chronically UV-irradiated skin of Skh:hr1 mice markedly inhibited tumor formation [279]. Treatment of normal human keratinocytes with  $1,25(\text{OH})_2\text{D}_3$  inhibited ERK $_{1/2}$  phosphorylation and phosphorylation of CREB [166,167], which may also contribute to reduced photo-carcinogenesis.

## 5. Conclusions

An overall summary of the mechanisms likely to contribute to reductions in photo-carcinogenesis by  $1,25(\text{OH})_2\text{D}_3$  and related compounds is shown in

**FIGURE 93.6A** Adverse effects of UV radiation on skin cells. Exposure to UV causes damage by absorption of photons resulting in direct DNA damage as well as mitochondrial damage and generation of reactive oxygen and nitrogen species. UV activation of PARP-1, which inhibits glycolysis, as well as mitochondrial damage, leads to energy depletion. The ROS and RNS generated cause damage to DNA bases, contribute to immune suppression, and together with energy depletion inhibit DNA repair. DNA damage contributes to immune suppression. UV inhibits PTEN, which reduces DNA repair protein expression, but increases p53 expression in the nucleus, which leads to cell cycle arrest and facilitates DNA repair. Inadequately repaired DNA leads to mutations in key genes, which together with immune suppression results in skin neoplasia. UV exposure increases phosphorylation of CREB, while chronic UV results in increased activity of later stages of the electron transport chain providing energy and pyrimidine nucleotides important for neoplastic change.

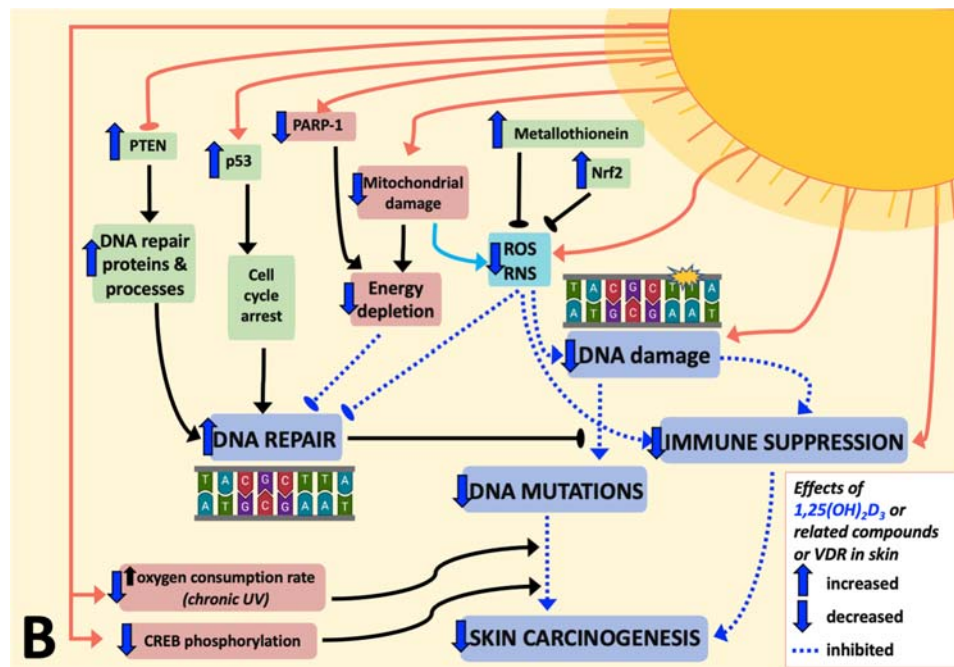

Fig. 93.6A,B. The hormone  $1,25(\text{OH})_2\text{D}_3$ , some naturally occurring related compounds, and specially synthesized derivatives predominantly alter cellular function by binding to the VDR and altering transcription [168,171]. The VDR may have functional effects without ligand. A variety of vitamin D compounds and many others, some of which are not cholesterol derivatives, including curcuminoids and other compounds, seem to be able to activate nonclassical pathways, possibly by binding to the alternate pocket on the VDR [150,155,171]. If, as the evidence suggests, nonclassical pathways contribute to photoprotection, many photoproducts of 7-dehydrocholesterol and their derivatives, including metabolites of vitamin D, such as  $25(\text{OH})\text{D}_3$  and the hormone, as well as CYP11A1 metabolites such as  $20(\text{OH})\text{D}_3$  and derivatives of overirradiation products such as  $24\text{-hydroxylumisterol}_3$  and related compounds, could contribute to reductions in UV-induced DNA damage and immune suppression. UV-adaptive mechanisms including increased pigmentation, increased thickness of the outer stratum corneum together with skin synthesis of vitamin D and related compounds are triggered by and develop after the first exposure to UV and so help to protect against subsequent exposures. Given this, it is highly likely that these

protective mechanisms would be more effective in practice if they developed gradually, under conditions of slowly increasing UV exposure during spring, as would normally be the case in hunter-gatherer societies.

## 6. Summary points

- Exposure of skin cells to UV causes DNA damage and immune suppression.
- Exposure of skin to UVB converts 7-dehydrocholesterol to pre-vitamin D, which converts to vitamin  $\text{D}_3$  at body temperature.
- 25- and  $1\alpha$ -hydroxylases in skin produce  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}_3$ .
- Both pre-vitamin D and vitamin  $\text{D}_3$  can absorb further UVB photons to form over-irradiation products, which are, in turn, acted on by CYP11A1 to form additional metabolites in skin.
- Vitamin D compounds in skin reduce UV-induced DNA damage by several mechanisms including reduced ROS/RNS, increased energy from glycolysis for repair, increased DNA repair proteins and processes, in part through increased PTEN and p53 and with a requirement for VDR and ERp57.

**FIGURE 93.6B** Effects of  $1,25(\text{OH})_2\text{D}_3$ , related compounds, and the VDR on skin cells following UV radiation. Working via the VDR and at least in part, requiring ERp57,  $1,25(\text{OH})_2\text{D}_3$ , and some related compounds reduce DNA damage by reducing reactive oxygen and nitrogen species at least in part through increased metallothionein, increased Nrf2 transcriptional activity, and more efficient mitochondrial repair. The vitamin D compounds also enhance DNA repair by both NER and BER, through increased provision of energy via glycolysis via reductions in PARP-1 activity, decreased ROS and RNS, maintenance of increased p53, and increased expression of repair proteins, partly through increased PTEN. These processes should result in decreased DNA mutations. The reduced DNA damage, increased DNA repair, and reduced ROS/RNS reduce UV-induced suppression of adaptive immunity. Fewer mutations and reduced immune suppression, together with reduced CREB phosphorylation and reduced activation of oxidative phosphorylation, result in less skin tumor formation after chronic UV exposure.

- Vitamin D compounds added topically reduce skin inflammation after UV in mice and reduce UV-induced immune suppression of the adaptive system in some mouse models in a sex-dependent manner.
- Mice that do not express VDR in skin are more susceptible to chemical- and UV-induced skin cancers.
- Applied topically after each dose of chronic UV,  $1,25(\text{OH})_2\text{D}_3$  and some vitamin D-like compounds, but by no means all, reduce UV-induced skin tumors in mice.
- VDR receptor polymorphisms and vitamin D status modify skin tumor development and prognosis in people in a complex manner.

# Vitamin D and antibacterial immunity

Aiten Ismailova<sup>1</sup> and John H. White<sup>1,2</sup>

<sup>1</sup>Department of Physiology, McGill University, Montreal QC, Canada <sup>2</sup>Department of Medicine, McGill University, Montreal QC, Canada

## OBJECTIVES

- Present mechanisms of vitamin D–regulated antibacterial immunity as evidenced by in vitro data.
- Provide an update on our ongoing understanding of prominent antibacterial immune actions of vitamin D.
- Describe new, lesser-known antibacterial effects of vitamin D.
- Establish a mechanistic basis for the link between 1,25(OH)<sub>2</sub>D and antibacterial immunity with in vivo studies that have reported improved immune health with vitamin D supplementation.

## 1. Introduction

The hormonal form of vitamin D (calcitriol or 1,25(OH)<sub>2</sub>D) is best known for its role in calcium and phosphate homeostasis, as detailed in other chapters in this book. However, since the 1980s, the number of studies on the extraskeletal, so-called nonclassical actions of vitamin D has grown exponentially. In particular, these provide increasing evidence for a role of 1,25(OH)<sub>2</sub>D signaling in regulation of the immune system. In vertebrates, the immune system can be separated into the innate and adaptive arms. The function of vitamin D in overseeing adaptive immunity is covered in Chapter 96 by Hawrylowicz et al. Contrary to the adaptive immune system, innate immune responses are hard-wired and provide front-line protection upon

detection of pathogenic threat. They are initiated by signaling via so-called pattern recognition receptors (PRRs). PRRs detect various receptor-specific pathogen- and damage-associated molecular patterns (PAMPs and DAMPs) [1]. PAMPs include components of bacterial cell walls or membranes and bacterial flagellin, while DAMPs, such as extracellular ATP, are endogenous molecules released in response to sterile inflammation. Among other responses, PRR signaling promotes the production of antimicrobial peptides, such as cathelicidin antimicrobial peptide (CAMP/LL-37) and  $\beta$ -defensin 2 (DEFB2/DEFB4/HBD2), which have direct antibacterial as well as antiviral activities. In humans, CAMP is produced initially as an 18-kDa protein, hCAP18, which is then cleaved to release the active 37-amino-acid peptide, LL-37 [2]. In addition, activation of PRRs induces the production of cytokines, which act to recruit other constituents of the immune system to sites of infection. As described in the following, expression of the genes encoding CAMP/LL-37 and HBD2 is directly induced by the hormone-bound VDR. Since this discovery, several studies have focused on the capacity of vitamin D to promote innate antimicrobial responses, which will be the main focus in this chapter. Antiviral activity of vitamin D will be covered in Chapter 95.

Interest in the nonclassical mechanisms of vitamin D action was stimulated by the observations that the vitamin D receptor (VDR) and the 25-hydroxyvitamin D 1 $\alpha$ -hydroxylase enzyme (1 $\alpha$ -OHase) were expressed in various tissues not connected with calcium and phosphate homeostasis [3–5]. Notably, both the VDR and 1 $\alpha$ -OHase are expressed in cells of the innate and adaptive arms of the immune system [6–8] (see Chapter 9); in addition to its induction by PRR signaling, expression of

*CYP27B1*, the gene encoding  $1\alpha$ -OHase, in immune cells is regulated by noncalcium inputs such as IFN- $\gamma$  and other cytokines including TNF- $\alpha$ , interleukin (IL)-1, and IL-2 [9]. The pathogen-dependent local production of  $1,25(\text{OH})_2\text{D}$  in immune cells was first demonstrated in 2000 by Overbergh et al., who found that, in response to bacterial lipopolysaccharide (LPS) and IFN- $\gamma$ , *Cyp27b1* expression in mice was induced in macrophages [7]. The bacterial ligand, LPS signals through Toll-like receptor 4 (TLR4), a member of a family of PRRs related to the protein encoded by the *Toll* gene in *Drosophila*. LPS signaling in human macrophages also upregulates expression of *CYP27B1* [8]. Consistent with these findings, increased *CYP27B1* expression and endogenous  $1,25(\text{OH})_2\text{D}$  production were also observed in human macrophages challenged with the ligand of TLR1/2 heterodimers to model immune responses to detection of *Mycobacterium tuberculosis* (*M.tb.*) [10].

Associations between vitamin D status (or sunlight exposure) and infections have been established since the time of ancient Greeks, where heliotherapy (sun therapy) was often practiced to treat phthisis (tuberculosis, TB) [11]. Moreover, cod liver oil, a rich source of vitamin D, was first reported as a treatment for chronic rheumatism in the 18th century. Over the next century, vitamin D was also shown to be effective in treating gout and scrofula, a form of TB infecting the lymph nodes [12]. The notion of treating TB via sunlight became popular with the advent of the sanatorium movement in Europe in the mid-19th century, when incidence of the disease peaked [13,14]. Furthermore, Niels Finsen, who received the Nobel Prize for Medicine in 1903, demonstrated that exposure to UV light was efficacious against cutaneous TB, or lupus vulgaris [13,14]. A more in-depth focus on vitamin D signaling in tuberculosis is provided in Chapter 98 by Martineau et al. In more recent years, support for potential preventative roles for vitamin D in septic shock, autoimmune disease (such as type 1 diabetes and multiple sclerosis), and infectious diseases (for instance, respiratory tract infections), as well as cancer, has been provided by epidemiological observations [15–18]. Evidence from laboratory and preclinical studies examining the immune mechanisms of action of  $1,25(\text{OH})_2\text{D}$ , as well as clinical data on vitamin D supplementation and risk of immune disease, will be explored in the following section.

## 2. $1,25(\text{OH})_2\text{D}$ , barrier integrity, and complement activation

Maintenance of barrier integrity is critical to several immune processes [19]. The gut is comprised of a plethora of commensal bacteria and other immune

system-activating substances in the lumen that can lead to mucosal inflammation [20]. The body is kept clear of luminal microbes and inflammatory substances by the gut mucosal epithelial barrier. An impaired gut mucosal barrier leads to an increased risk of inflammatory bowel disease (IBD), which include Crohn's disease (CD) and ulcerative colitis (UC) [21].  $1,25(\text{OH})_2\text{D}$  signaling has been shown to be critical in barrier homeostasis (see Chapter 97). This was most clearly demonstrated by the research group of Yan Chun Li and others, who showed that widespread deletion of the *Vdr* compromised mucosal barrier integrity, which led to increased mortality in a dextran sulfate sodium (DSS)–induced colitis model [22–24]. In the DSS model, *Vdr* knockout mice presented decreased colonic transepithelial electrical resistance, an established marker of epithelial barrier integrity [23]. Moreover, human *VDR* transgenic mice, which exhibit a 2–3 fold increase in *VDR* expression in the gut, displayed substantial resistance to colitis relative to wild-type control mice [25]. To show that epithelial-specific *VDR* has a role in anticolic activity, Li et al. reconstituted gut epithelial cells from human *VDR* transgenic mice in *Vdr* knockout mice. Following introduction of the *VDR* to *Vdr*<sup>−/−</sup> gut epithelial cells, the resulting mice were highly resistant to colitis, suggesting epithelial *VDR* signaling is accountable for preventing mucosal inflammation [25]. The cause of increased mucosal permeability in the *Vdr*<sup>−/−</sup> mice was attributed to increased gut epithelial cell apoptosis [26]. Interestingly,  $1,25(\text{OH})_2\text{D}$  suppresses intestinal epithelial cell apoptosis via inhibition of NF- $\kappa\text{B}$  activity, which is thought to be the main mechanism by which the hormone maintains intestinal barrier integrity [25].

In addition, the complement system is an integral component of innate immunity critical to enhancing (complementing) the capacities of antibodies and immune cells to clear pathogens. It also modulates adaptive immune responses. Briefly, in response to pathogen- or danger-sensing immune complexes (classical pathway) or danger-sensing (lectin pathway), the proenzyme complement 3 (C3) is activated to produce active C3a and C3b proteolytic fragments [27]. C3a and b in turn recruit and trigger activation of immune cells and downstream components of complement (C5–C9) [27]. Notably,  $1,25(\text{OH})_2\text{D}$  exerts an effect on this facet of innate immunity. In macrophages, mRNA and protein expression of complement receptor immunoglobulin (CRIg), responsible for phagocytosis and bacterial clearance, is upregulated in response to  $1,25(\text{OH})_2\text{D}$  [28]. This increase was linked with an amplification in phagocytosis of complement opsonized bacteria and fungi. In addition,  $1,25(\text{OH})_2\text{D}$  appears to attenuate the effects of complement signaling on chemotaxis of neutrophils, the first innate immune cells to sites of inflammation and infection. Function of the complement factor 5a (C5a),

**FIGURE 94.1** Antibacterial activity of vitamin D in response to infections in the monocyte/macrophage. See text for details.

chemotactic for neutrophils, is enhanced by the transport protein for vitamin D (vitamin D binding protein or DBP) [29]. However, binding of DBP to physiological concentrations of 1,25(OH)<sub>2</sub>D counteracted this neutrophil chemotaxis [30]. Consistent with its antiinflammatory role, 1,25(OH)<sub>2</sub>D can also modulate inflammatory responses of adaptive CD4<sup>+</sup> type 1 helper (T<sub>H</sub>1) cells following complement activation [31]. Complement was shown to mediate retraction of T<sub>H</sub>1 cell responses via induction of VDR and CYP27B1 expression. The ensuing 1,25(OH)<sub>2</sub>D signaling promoted the conversion of proinflammatory interferon-γ<sup>+</sup> T<sub>H</sub>1 cells to suppressive interleukin-10<sup>+</sup> cells. Intriguingly, bronchoalveolar lavage fluid CD4<sup>+</sup> T cells of patients afflicted with COVID-19 demonstrated derepression of genes downregulated by vitamin D [31].

### 3. 1,25(OH)<sub>2</sub>D induces antimicrobial peptides implicated in antibacterial immunity

1,25(OH)<sub>2</sub>D can directly contribute to the host responses against pathogens by activating the

transcription of a number of genes encoding proteins implicated in innate immunity, including antibacterial peptides (AMPs), pattern recognition receptors, cytokines, and components of autophagic responses (Fig. 94.1). In 2004, our laboratory found vitamin D response elements (VDREs) near the transcription start sites of two genes that encode the AMPs cathelicidin antimicrobial peptide (CAMP/LL-37) and β-defensin 2 (DEFB2/DEFB4/HBD2) [32]. Following 1,25(OH)<sub>2</sub>D treatment, CAMP expression was robustly induced in myeloid and bronchial epithelial cells, as well as keratinocytes [10,33,34]. CAMP transcription was also enhanced by 1,25(OH)<sub>2</sub>D in monocytes exposed to *M.tb*. [35]. Notably, activation of cathelicidin is suggested as a likely pathway through which 1,25(OH)<sub>2</sub>D induces innate immune responses to *M.tb*., as reported by studies using short interfering RNA to block 1,25(OH)<sub>2</sub>D-mediated CAMP expression [36].

Although only modest direct induction of DEFB4 was observed in cells treated with 1,25(OH)<sub>2</sub>D alone, 1,25(OH)<sub>2</sub>D substantially enhanced DEFB4 transcription induced by interleukin (IL)-1β [32]. Mechanistically,

signaling by IL-1 $\beta$  promotes binding of NF- $\kappa$ B transcription factor members to promoter-proximal sites in the *HBD2* promoter [37]. In accordance with these findings, exposure to 1,25(OH) $_2$ D promoted secretion into conditioned media antibacterial activity against *Escherichia coli* and the lung pathogen, *Pseudomonas aeruginosa* [32]. The induction of AMPs by 1,25(OH) $_2$ D may confer protection against other bacterial and nonbacterial pathogens, as human cathelicidin was reported to inhibit HIV-1, Ebola, and influenza A viral replication [38–40], and expression of defensins is augmented upon infection by *Helicobacter pylori* and rhinovirus [41,42]. Further, beta defensins were shown to inhibit HIV-1 replication in macrophages [43] and biofilm production of *P. aeruginosa* [44].

The link between 1,25(OH) $_2$ D-mediated *CAMP* transcription and protection against bacterial infections has been reinforced by several publications. For instance, topical administration of 1,25(OH) $_2$ D to the skin of transgenic mice carrying the human *CAMP* gene under control of its own promoter enhanced *CAMP* expression and augmented killing of *Staphylococcus aureus* as part of a model of wound infection [45]. Moreover, in respiratory epithelial (A549) cells infected with human rhinovirus (RV-16), pretreatment with physiological concentrations of 25(OH)D reduced expression of the platelet-activating factor receptor, involved in adhering *Streptococcus pneumoniae* to respiratory cells [46]. Notably, this decrease was correlated with a robust induction of *CAMP* expression, providing a mechanism by which vitamin D can attenuate the risk of secondary bacterial infection in vitamin D–deficient individuals infected with rhinovirus [46]. An additional role for 1,25(OH) $_2$ D-induced *CAMP* in enhancing pregnant innate immune defenses was suggested by Chin-Smith et al. [47]. In their study, 1,25(OH) $_2$ D was found to promote *CAMP* expression in the presence of inflammatory agents IL-1 $\beta$  and LPS in human endocervical epithelial cells [47].

Hepcidin antibacterial protein (HAMP) is another AMP regulated by 1,25(OH) $_2$ D. Although there is no direct microbial activity of HAMP, it was shown to inhibit ferroportin-facilitated export of iron and contribute in anemia of infection or inflammation. Diminishing level of iron in the circulation is a critical immune response to systemic infection, as several microorganisms require iron for their growth [48]. Further, infectious and immune stimuli enhance expression of HAMP, as demonstrated by mouse models of *Candida albicans* and influenza A/PR/8/34 virus infections [49]. Interestingly, Hewison and coworkers found that the 1,25(OH) $_2$ D-bound VDR transcriptionally inhibited *HAMP* expression in monocytes and hepatocytes [50]. Similar results were also obtained by Zughaier et al.,

who found increasing concentrations of 1,25(OH) $_2$ D correlated with suppressed hepcidin mRNA expression [51]. A decrease in *HAMP* induction was accompanied by an increase in the expression of ferroportin and a decrease in ferritin expression, which provides an indication for levels of intracellular iron [50]. Contrary to DEFB4 and *CAMP*, increased circulating 25(OH)D levels are associated with decreased amounts of serum HAMP. Nevertheless, like with defensins and cathelicidin, 1,25(OH) $_2$ D binds to specific VDREs in the *HAMP* promoter to directly repress its expression [50].

#### 4. 1,25(OH) $_2$ D and autophagy

Vitamin D signaling may also combat intracellular infections via induction of autophagy (Fig. 94.1). A compelling example of a role for vitamin D–induced autophagy is in infections with *M.tb.*, the etiological agent of tuberculosis. In macrophages, phagosome-resident *M.tb.* can escape host antimicrobial mechanisms via inhibiting the maturation of phagosomes and their fusion with lysosomes [52]. To conquer this evasion strategy, the host must degrade phagosomes containing bacteria via autophagy and subsequently destroy the bacteria in autolysosomes [53,54]. Interestingly, 1,25(OH) $_2$ D-mediated *CAMP* production enhanced autophagy in macrophages infected with mycobacteria, as demonstrated in an in vitro study by Yuk et al. [55]. The authors subsequently found that blocking 1,25(OH) $_2$ D-mediated autophagy with pharmacological inhibitors or siRNA against *CAMP* led to an increase in bacterial burden in infected macrophages. This study showed for the first time that physiological amounts of 1,25(OH) $_2$ D can initiate autophagy in infected macrophages to promote the elimination of *M.tb.* Further support for 1,25(OH) $_2$ D-induced *CAMP* in promotion of autophagy came from studies that revealed, in 1,25(OH) $_2$ D-exposed cells, *CAMP* was colocalized with mycobacteria in phagolysosomes [56]. In another study, autophagy was induced by 1,25(OH) $_2$ D in TLR2/1-agonist-stimulated macrophages isolated from 25(OH)D-deficient human populations, although the role of *CAMP* was not assessed [57].

Apart from induction of *CAMP* expression, there exist other mechanisms by which 1,25(OH) $_2$ D can trigger autophagy. 1,25(OH) $_2$ D-bound VDR also induces expression of the PRR NOD2, as well as ATG16L1, whose functions are linked to autophagy [58,59] (Fig. 94.1). Interestingly, the two proteins are connected, as NOD2 bound to muramyl dipeptide, the lysosomal breakdown product of bacterial peptidoglycan, recruits ATG16L1 to the plasma membrane upon bacterial entry and prompts subsequent autophagy and pathogen

clearance [60] (Fig. 94.1). However, this process was abrogated in cells homozygous for mutations in *NOD2* or *ATG16L1* [60]. These results are highly significant as *NOD2* and *ATG16L1* have been identified as susceptibility loci in genome-wide association studies of patients with Crohn's disease, relapsing-recurring IBD [61–65]. This links (loss of) vitamin D signaling to CD, and CD to impaired autophagic responses to intestinal bacterial flora. Other studies also link VDR function to autophagy. Murine intestinal epithelium lacking the *Vdr* presents an imbalance of autophagy and apoptosis [66,67]. Decreases in lysozymes and autophagic responses, as defined by reduced expression of *ATG16L1* and the autophagosome-marker LC3, were reported in IBD-susceptible, Paneth cell-specific VDR knockout mice [68]. The impaired autophagy presented by these mice was associated with depleted intestinal microbiota and prolonged proinflammatory cytokine production, as well as decreased bacterial clearance in the context of *Salmonella* infection [68]. In addition, the *Vdr* is a master transcriptional regulator of autophagy in normal and tumorigenic mammary gland cells [69]. Furthermore, our laboratory showed that 1,25(OH)<sub>2</sub>D suppressed activation of a repressor of autophagy, the major metabolic kinase mammalian target of rapamycin (mTOR) in macrophages. This regulation was dependent on the activation of branched-chain amino acid (BCAA) catabolism [70]. BCAAs are essential amino acids and act as metabolic signals in myeloid cells. High BCAA levels activate mTOR, which enhances metabolically expensive processes such as protein synthesis and suppresses autophagy. 1,25(OH)<sub>2</sub>D-induced autophagy was found to be abolished in cells in which the gene encoding branched-chain aminotransferase, *BCAT*, the rate-limiting catabolizing enzyme of BCAAs, was ablated [70]. This finding is corroborated by a previous report on synthetic 1,25(OH)<sub>2</sub>D analogs inhibiting mTOR activity, resulting in autophagy in various cancer cell lines [71]. Further, a study by Song et al. found that 1,25(OH)<sub>2</sub>D treatment restored autophagy, via induction of autophagy-associated proteins such as Beclin-1, in podocytes from patients with diabetic nephropathy compared with healthy controls [72].

## 5. 1,25(OH)<sub>2</sub>D promotes expression of pattern recognition receptors and cytokines

Another facet of 1,25(OH)<sub>2</sub>D signaling in innate immunity is encompassed by the regulation of PRR and cytokine expression (Fig. 94.1). In the early 1990s, the gene that encodes the TLR4 coreceptor, *CD14*, was determined to be a target gene of 1,25(OH)<sub>2</sub>D [73]. *CD14*

serves as a coreceptor for multiple other TLRs, such as TLR1/2 [74], which, like TLR4, responds to bacterial ligands, as well as the viral-sensing TLRs, TLR7 and TLR9 [75]. Following TLR activation, antimicrobial peptides and reactive oxygen species (ROS) are induced, which help to destroy microorganisms. Although excessive ROS can result in cellular damage, 1,25(OH)<sub>2</sub>D can keep this in check by promoting expression of antioxidant genes such as glutathione synthase [76]. Moreover, 1,25(OH)<sub>2</sub>D upregulates the intracellular pathogen-sensing protein *NOD2/CARD15/IBD1* in myeloid and epithelial cells [77]. Thus, in cells pretreated with 1,25(OH)<sub>2</sub>D to induce *NOD2*, its cognate ligand muramyl dipeptide superinduces *CAMP* and *DEFB4* expression via induction of NF-κB signaling. However, this cooperative induction of *DEFB4* is eliminated in patients carrying inactivating *NOD2* mutations afflicted with CD [77]. Individuals who are heterozygous or homozygous for nonfunctional mutations of the *NOD2* gene bear higher risks of developing CD by 3-fold and 20-fold, respectively [78]. Moreover, the *DEFB4* locus has undergone a series of gene duplication events, and individuals with low copy number of *DEFB4* are also at increased risk of developing colonic CD [79]. This implicates defective induction of the *NOD2-DEFB4* pathways as a risk factor for CD.

1,25(OH)<sub>2</sub>D may also repress expression of PRRs, as shown in a study of *M.tb.*-infected human peripheral blood mononuclear cells, where 1,25(OH)<sub>2</sub>D-bound VDR-repressed TLR2, TLR4, dectin-1, and mannose receptor [80]. This suppresses the production of proinflammatory cytokines IL-6, TNF-α, and IFN-γ, consistent with an antiinflammatory role for 1,25(OH)<sub>2</sub>D signaling. IL-6 and TNFα were also inhibited by 1,25(OH)<sub>2</sub>D in LPS-treated human and murine monocytes and macrophages [81,82]. Further, 1,25(OH)<sub>2</sub>D synergistically functions with other signals to modulate cytokine expression; for instance, glucocorticoid-induced suppression of IL-6 in LPS-challenged human monocytes was enhanced upon 1,25(OH)<sub>2</sub>D treatment [83]. However, not all cytokines and chemokines regulated by 1,25(OH)<sub>2</sub>D are repressed, which serves to modulate the immune response. IL-1β, a cytokine secreted in response to infection, is directly induced by the hormone in human myeloid cells [84]. The functional importance of this was shown in a coculture of primary human airway epithelial cells with macrophages infected with *M.tb.*; this coculture system revealed that 1,25(OH)<sub>2</sub>D- and *M.tb.*-induced IL-1β secretion prolonged survival of infected macrophages and decreased *M.tb.* burden in those cells by inducing *DEFB4* production in the cocultured lung epithelial cells. 1,25(OH)<sub>2</sub>D also robustly upregulated the chemokines, *CCL3*, *CCL4*, and *CCL8*,

**FIGURE 94.2** Mechanisms of vitamin D signaling following exposure to bacteria in the gut epithelial cell. See text for details.

as well as the neutrophil chemoattractant, IL-8/CXCL8 [84]. In addition,  $1,25(\text{OH})_2\text{D}$  can indirectly promote cytokine expression through CAMP induction; LL-37, the active peptide encoded by CAMP, can trigger the release of antiinflammatory IL-10 and proinflammatory IL-18 cytokines [85]. A summary of vitamin D signaling in the monocyte and gut epithelial cell is provided by Figs. 94.1 and 94.2, respectively.

## 6. $1,25(\text{OH})_2\text{D}$ regulates release of reactive oxygen species

$1,25(\text{OH})_2\text{D}$  can also enhance bacterial killing through induction of ROS, which are defined by a class of endogenous, highly reactive, oxygen (and nitrogen)-bearing molecules that are directly antimicrobial. In the presence of  $1,25(\text{OH})_2\text{D}$ , monocytes infected with *M.tb.* generate an increased amount of bactericidal superoxide anions [86]. Further,  $1,25(\text{OH})_2\text{D}$ -mediated repression of *M.tb.* growth in monocytes may be associated with production of nitric oxide (NO) [87,88], which has been previously shown to serve a critical bactericidal mechanism in infected mice [89]. However,  $25(\text{OH})\text{D}$  deficiency resulted in increased ROS release and DNA damage, which consequently led to exacerbated asthma [90], a condition where the innate immune system plays a critical role [91]. The same study reported vitamin  $\text{D}_3$  inhibited LPS-induced ROS, which was associated with decreased levels of  $\text{TNF-}\alpha$  and  $\text{NF}\kappa\text{B}$  in epithelial

cells [90]. The role of vitamin D in asthma is explored further in Chapter 105 by Dr. Camargo.

## 7. Evolutionary aspects of $1,25(\text{OH})_2\text{D}$ induction of AMPs and PRRs

It is important to note that many mechanisms of  $1,25(\text{OH})_2\text{D}$ -mediated innate immune signaling appear to be limited to humans and primates. This was made clear through observation of conserved VDREs in *HBD2*, *CAMP*, and *NOD2* genes in primates, but not in rodents [92]. Notably, the VDRE in the *CAMP* gene is present within an Alu repeat element existing only in primate and human genomes [33]. The transposition event occurred before the evolutionarily split Old and New World monkeys [93]. Further support for the notion of species specificity emerged from in vitro studies where no induction of *Defb2*, *Cramp* (the murine homolog of *CAMP*), and *Nod2* genes was observed in  $1,25(\text{OH})_2\text{D}$ -treated murine cells of epithelial or myeloid origin. In addition, unlike in control human cells, induction of antimicrobial activity against *E. coli* or *P. aeruginosa* was undetectable in  $1,25(\text{OH})_2\text{D}$ -treated mouse epithelial cells [33]. However, it is noteworthy that in mice lacking *Cyp27b1*, *Cd14* induction by  $25(\text{OH})\text{D}$  was abrogated [94], and agonists of TLR signaling promoted murine macrophage *Cyp27b1* expression [7]. Thus, the TLR coreceptor gene *Cd14* appears to be a VDR target gene in human and mouse.

Separate mechanisms of 1,25(OH)<sub>2</sub>D regulation of AMPs in humans and mice can be attributed to the nocturnal nature of mice, while humans are diurnal and, as a result, can synthesize active vitamin D from sunlight [10]. The expanded role of 1,25(OH)<sub>2</sub>D in innate immunity of humans/primates may have evolved as a protective response to sun exposure. Further, differences in human and murine immune systems can be attributed to distinct sites of 1,25(OH)<sub>2</sub>D synthesis, as CD8<sup>+</sup> T cells rather than macrophages are suggested as the primary immune cell source of *Cyp27b1* expression and activity in mice [95].

## 8. 1,25(OH)<sub>2</sub>D and neutrophils

The majority of studies thus far have explored regulation of the innate immune response by vitamin D in cells of monocytic or epithelial origin. Yet, there are a number of other immune cell types that express PRRs and hence carry the essential machinery required to initiate innate immune reactions to microbial threat. Neutrophils are the most numerous among the granulocyte population, and patients with congenital neutrophil insufficiencies are frequently afflicted with severe infections, emphasizing the significance of this cell type in immune defense [96]. Upon microbe invasion, these short-lived cells become “activated,” a term referring to the neutrophil’s integration of environmental signals and translation into specific actions. During its pursuit of pathogens, the neutrophil mobilizes secretory vesicles and granules, traverses via chemotactic gradients to sites of infection/inflammation, and starts transcribing cytokine genes to recruit more immune cells and releasing its arsenal of antimicrobial defense. Neutrophils also contain and produce a large amount of cytotoxic molecules; this is mainly on account of factors stored in their granules, such as antibacterial enzymes (e.g., myeloperoxidase [97]) and peptides (e.g., defensins [98]), in addition to serine proteases (e.g., neutrophil elastase [99]). Methods of microbial killing by neutrophils include phagocytosis, degranulation, production of ROS (respiratory burst), and release of neutrophil extracellular traps (NETs). NETs are structures of extracellular fibers composed of DNA, citrullinated histones (H3Cit), and antimicrobial enzymes that function to immobilize pathogens [96]. However, the killing of invading microorganisms by these cells requires careful control of neutrophil function, as neutropenia results in vulnerability to infection, whereas overactivity is linked with inflammatory diseases [100]. Phagocytosis generally expedites neutrophil apoptosis, which eventually results in the resolution of infection or inflammation [101]. Conversely, a

number of bacteria modify and inhibit neutrophil apoptosis to extend their survival and hence cause disease [101].

The literature to date on the effect of vitamin D on neutrophil biology is not extensive. Human neutrophils express *VDR* mRNA to a similar extent to monocytes, and upon exposure to 1,25(OH)<sub>2</sub>D, promote *CD14* and *CAMP* expression [32,102]. However, contrary to monocytes, it is not apparent that these granulocytic cells express *CYP27B1*, suggesting that they are more likely to respond systemically to circulating hormonal 1,25(OH)<sub>2</sub>D. Neutrophils may be exposed to paracrine 1,25(OH)<sub>2</sub>D produced via innate immune signaling described before at sites of infection. Regardless, because of their abundance and development of granules that carry the bulk of LL-37 secreted at sites of infection, neutrophils are the predominant source of serum cathelicidin [103,104]. In patients with chronic kidney disease, there is a strong link between decreased serum LL-37 and mortality, and levels of LL-37 correlated with serum 1,25(OH)<sub>2</sub>D, rather than 25(OH)D. This may represent an endocrine-mediated immune response involving neutrophils with low *CYP27B1* and high *VDR* expression [105,106]. However, this is not universal, as in septic patients with a sustained high numbers of neutrophils, circulating LL-37 is lower in severe cases and is linked with low serum 25(OH)D [107].

Takahashi et al. in the early 2000s found that 1,25(OH)<sub>2</sub>D modestly suppressed LPS-induced neutrophil elastase inhibitor trappin-2/elafin/SKALP and IL-1β in human primary neutrophils [102]. Further, increased apoptosis in COPD patient neutrophils was observed after 1,25(OH)<sub>2</sub>D treatment [108]; this is remarkable given that a decreased rate of neutrophil apoptosis is characteristic of the disease, and vitamin D offset granulocytic cell death through activation of p38 MAPK. The hormone was also reported to strongly boost IL-8 secretion in *M.tb.*-infected macrophages [84] as well as LPS-challenged neutrophils [109]; however, no impact on phagocytosis was noted when cells were infected with *E. coli* [109]. On the contrary, 1,25(OH)<sub>2</sub>D can inhibit neutrophil degranulation as determined by release of myeloperoxidase activity and ROS production in an inflamed mouse model of carrageenan-induced paw edema [110]. Moreover, neutrophil killing of the bacterium, *Streptococcus pneumoniae*, was increased with 1,25(OH)<sub>2</sub>D treatment, and expression of the antiinflammatory cytokine IL-4 and suppressor of cytokine signaling (SOCS) proteins were induced by the hormone, suggesting a role for vitamin D in inhibiting neutrophil-mediated inflammatory responses while still promoting microbial killing [111]. Agraz-Cibrian et al.’s pilot study showed that 1,25(OH)<sub>2</sub>D enhanced formation of NETs [112].

However, it should be noted that the structures observed were not confirmed to be genuine NETs in this study [112].

### 9. 1,25(OH)<sub>2</sub>D and natural killer cells

Natural killer (NK) cells are often reported to serve as the link between innate and adaptive immunity [113]. Although there are studies suggesting no effect of 1,25(OH)<sub>2</sub>D on NK cells [114–116], others indicate a role for the hormone in this cell type [117–125]. Dysregulated NK cell activity is a hallmark of patients with vitamin D metabolic disorders such as vitamin D-resistant rickets and chronic renal failure [117,118]. Upon supplementation with vitamin D, normalized activity of NK cells began to appear in these patients. Further, low serum 25(OH)D was linked with impaired NK cytolytic function among a population of healthy elderly people [121]. In vitro studies corroborate the in vivo results, as treatment with 1,25(OH)<sub>2</sub>D dose-dependently increased the number of cellular granules and reduced the delay in granzyme A secretion in NK cells, both markers of enhanced NK activity [119,122]. In addition, a regulatory NK cell phenotype, where T cell responses are repressed, was induced by 1,25(OH)<sub>2</sub>D; this was made evident with upregulated antiinflammatory IL-10 cytokine mRNA in response to the sunshine hormone and glucocorticoid dexamethasone in NK cells [120]. Along with regulating proinflammatory NK function, a contribution by 1,25(OH)<sub>2</sub>D to enhancing NK cell cytotoxicity was also suggested [123–125].

### 10. 1,25(OH)<sub>2</sub>D and nonclassical immune cells

Antibacterial activity of vitamin D has also been depicted in cell types extrinsic to the classical immune system. For instance, as previously mentioned, 1,25(OH)<sub>2</sub>D promotes increased expression of LL-37 in keratinocytes [33]. However, in contrast to monocytes, the mechanism behind this is not related to TLR2-TLR1 activation. Rather, soluble factors, including transforming growth factor  $\beta$ 1 (TGF- $\beta$ 1), are necessary to induce expression of *CYP27B1* and local production of 1,25(OH)<sub>2</sub>D [94]. The increased concentrations of 1,25(OH)<sub>2</sub>D and *VDR* expression subsequently promote induction of *TLR2* gene expression in keratinocytes. The ensuing high levels of *TLR2* allow increased responsiveness to infectious agents and additional *CYP27B1* and *VDR* expression mediated by a TLR2-dependent mechanism [94]. In this manner, there is vitamin D-induced intracrine production of cathelicidin in keratinocytes, similar to that observed in monocytes. Epithelial wound

healing represents a scenario in which sufficient TGF- $\beta$ 1 is produced to promote keratinocyte antibacterial activity. The necessity for a dual mechanism to enable vitamin D-dependent antibacterial responses in the skin may be attributed to the various functions of cathelicidin. Not only is cathelicidin antibacterial, but it is also shown to modulate antigen presentation [126] and epidermal wound healing [127]. However, cathelicidin induces release of cytokines and chemokines, which in turn can exacerbate tissue inflammation [128–130]. For a detailed overview of the role of vitamin D in the skin, readers are referred to Chapter 25.

In addition to keratinocytes, vitamin D-facilitated intracrine production of cathelicidin appears during pregnancy in placental decidual (maternal) [131] and trophoblastic (fetal) cells [132]. Interestingly, vitamin D-induced CAMP activity in these cells does not occur via the same TLR-mediated induction of *CYP27B1* reported in cells from the skin or immune system. This difference may be attributed to the expression of *CYP27B1* and *VDR* being induced early in gestation, contributing to a high baseline level of 1,25(OH)<sub>2</sub>D synthesized endogenously in the placenta [133]. During pregnancy, the placenta represents a natural barrier to fetal infection, and both maternal and fetal tissues express antimicrobial proteins [134]. Thus, robust 1,25(OH)<sub>2</sub>D production in the placenta may explain the high baseline expression of antibacterial proteins to protect against infection by pathogens, including *Listeria monocytogenes*, which is involved in adverse effects linked with pregnancy [135]. More information on the effect of vitamin D signaling in the placenta is provided by Chapter 34.

Further, the cornea of the eye is a site for local inflammatory responses required for efficient wound healing and is sensitive to vitamin D signaling. The function of the hormone in the eye is explored extensively in Chapter 42. Corneal cells contain *VDR* and *CYP27B1* mRNA and show enhanced barrier function upon exposure to 1,25(OH)<sub>2</sub>D in vitro [136]. Improved barrier activity with 1,25(OH)<sub>2</sub>D treatment is also observed in an in vivo mouse model of corneal epithelial wound healing, and topical administration of the hormone increased production of murine c 12 h following wounding [137]. Increased CAMP mRNA expression following 1,25(OH)<sub>2</sub>D treatment was also reported in human corneal epithelial cells and was accompanied by a decrease in proinflammatory cytokine expression [138].

### 11. In vivo evidence for 1,25(OH)<sub>2</sub>D regulation of antibacterial innate immunity

There is ample clinical data supporting a role for 1,25(OH)<sub>2</sub>D in the regulation of antibacterial innate immunity. For example, antimicrobial activity of lung

airway surface liquid (ASL) was enhanced by supplementation with 1000 international units (IU; 25 µg) per day for 90 days of vitamin D, as reported by a single-center community-based randomized placebo-controlled double-blind trial [139]. In addition, enhanced antimicrobial activity in ASL was reported in the summer–fall season compared with winter–spring, and an anti-LL-37 antibody blocked ASL antimicrobial activity. Moreover, supplementing with vitamin D eliminated the seasonality of ASL antimicrobial activity [139]. The clinical significance of 1,25(OH)<sub>2</sub>D-induced CAMP production was also illustrated by a Swedish study that found a link between inadequate vitamin D levels and an elevated risk of dental caries [140]. Antimicrobial peptide production is critical for prevention of dental caries; decreased levels of antimicrobial peptides [141] and presence of *DEFB1* promoter polymorphisms [142] are linked with increased risk of caries. In the Swedish study, concentrations of CAMP in saliva correlated positively with vitamin D status in participants [140]. Likewise, a prospective cohort study in Spain found the risk of caries is tripled when 25(OH)D values were lower than 20 ng/mL among 188 children between 6 and 10 years of age [143]. This finding was also corroborated by cross-sectional, observational and randomized clinical investigations that place vitamin D deficiency as a risk factor for dental caries [144–146]. Similarly, a large-scale umbrella analysis of systematic reviews and metaanalyses of observational studies and randomized trials concluded that poor vitamin D status is a risk factor for dental caries [145]. Importantly, in this regard, CAMP/LL-37 is efficacious against bacterial species that are found in plaque, such as *Streptococcus mutans* [147]. In addition to dental caries, serum vitamin D concentration is linked with antimicrobial peptide levels in other diseases of oral health. For instance, gingivitis and chronic periodontitis patients who were vitamin D–deficient (25(OH)D levels of <20 ng/mL) presented decreased expression of HBD2 and LL-37, as determined by ELISA [148].

Poor serum 25(OH)D status is also associated with increased risk of urinary tract infections (UTI). In the urinary bladder, vitamin D signaling promotes CAMP expression [149], and urinary LL-37 is correlated with vitamin D status in children less than 3 years of age [150]. Clinically, vitamin D deficiency is linked with recurrent rates of UTI in infants, children, and premenopausal women [150–153]. A systematic metaanalysis including nine studies and 1921 participants, of which 580 were diagnosed with UTI, revealed that vitamin D deficiency was more prevalent in the UTI group [154]. The same study verified the robust correlation between vitamin D insufficiency and UTI in children [154]. Moreover, UTI is causally linked with the most common liver disease linked with obesity in the West: nonalcoholic

fatty liver disease (NAFLD) [155], which is exacerbated by vitamin D deficiency [156,157] and improved with vitamin D treatment [158]. Interestingly, there is a strong link between levels of gut microbial metabolites, such as bacterial-derived ethanol, and NAFLD progression [159,160]. Consistent with this, vitamin D affects intestinal innate immunity and gut microbial structure, for example, by regulating mucin gene expression [161] and ameliorating mucosal impermeability to bacterial endotoxin infiltration [162], which may provide a mechanism for its role in NAFLD. In addition, there is indirect evidence for AMPs regulated by vitamin D in dampening NAFLD; in diabetic mice fed a high-fat diet, NAFLD and fat mass were reduced upon lentiviral-driven overexpression of cathelicidin [163].

In CD, the inflammatory bowel condition arising from impaired intestinal innate immunity, patients often present with low levels of vitamin D [164]. Notably, vitamin D metabolite levels were associated with a decreased risk of CD recurrence, as determined by endoscopy [165]. Two metaanalyses have reanalyzed several small clinical studies on CD and vitamin D supplementation. Li et al. found diminished rates of relapse among vitamin D–treated CD patients relative to controls [166]. Likewise, low 25(OH)D status was associated with amplified IBD activity, mucosal inflammation, and ensuing clinical relapse in CD patients in a systematic review by Gubatan and colleagues [167]. Interestingly, while mutations in the gene encoding the PRR NOD2, whose expression is inducible by 1,25(OH)<sub>2</sub>D [32], are associated with susceptibility to CD in Western patients, they are not detected in afflicted Korean, Japanese, or Chinese CD patients [168]. Nonetheless, a cohort investigation conducted in South Korea found aggravated disease course and increased risk of surgical intervention were associated with severe vitamin D deficiency (<10 ng/mL) [169], findings consistent with other clinical studies of vitamin D status in Asian CD patients [170,171]. Mental health disorders are also common among individuals affected with CD, and a systematic review of 10 intervention studies conducted by Glabska et al. determined a positive association between vitamin D supplementation and the mental health of CD patients [172].

Decreased levels of circulating 25(OH)D are also prevalent, and correlate with, disease severity in chronic obstructive pulmonary disease (COPD) [173–177], although, overall, the data are conflicting (Chapter 105). COPD is an airway inflammatory condition with chronic bacterial infection as one of its causes [178]. Support for the role of vitamin D in COPD was provided by a randomized, double-blinded, placebo-controlled trial, which recruited 442 adults to receive a monthly high-dose (100,000 IU or 2500 mcg) of vitamin D<sub>3</sub> for 1.1 years [179]. Although the study did not find significantly

improved lung function, as measured by decreased forced expiratory volume in 1 s (FEV1), in the total population, vitamin D<sub>3</sub> supplementation was of benefit in participants with existing lung problems such as asthma, COPD, or a history of smoking [179]. However, a metaanalysis of eight cohort and randomized controlled trials (RCTs) consisting of 687 COPD subjects determined no improvement in lung function with either short-term (<6 months) nor long-term (≥6 months) vitamin D<sub>3</sub> supplementation [180]. Another report combined three cycles of National Health and Nutrition Examination Surveys, and although, there was no relation between serum 25(OH)D and prevalence of asthma, chronic bronchitis, and emphysema among US adults, serum 25(OH)D was associated with ameliorated markers for lung effectiveness [181]. Overall, the clinical data for vitamin D supplementation in COPD is mixed, and additional large-scale, randomized and placebo-controlled controlled studies are required to assess the possible role of vitamin D in influencing the risk and course of COPD.

In addition, a low level of circulating vitamin D metabolites is likely to increase the risk for severity of sepsis, which is defined as the dysfunctional host response to an infection leading to organ failure. Vitamin D deficiency has been reported in several critically ill patients with sepsis, and interestingly, this was correlated with low amounts of LL-37 [182,183]. Patients with suspected infection and 25(OH)D insufficiency had higher sepsis severity, as measured by a sequential organ failure assessment greater than 2, than infected patients with sufficient vitamin D levels [184]. Vitamin D deficiency was a significant predictive marker of sepsis and displayed a 1.6-fold increase in mortality, as reported in a large two-center observational study including 3386 critically ill patients [185]. This is also corroborated by several studies on vitamin D and critically ill children with sepsis [186]. 25(OH)D deficiency is prevalent (64%) in children with sepsis and is linked with increased mortality, according to a systematic review of 18 studies evaluating 889 patients [187]. Moreover, low levels of vitamin D in cord and maternal blood were significantly associated with neonatal sepsis, based on a metaanalysis of 18 cohort and case-control studies [188]. Another metaanalysis found that vitamin D insufficiency was linked to a higher incidence of sepsis, severity of illness, and length of hospital stay [189]. However, other reports of pediatric sepsis and vitamin D deficiency demonstrate weak association with ventilation and mortality [190,191]. Furthermore, vitamin D levels in children with sepsis are not consistently correlated with levels of DBP or LL-37 [192–194], suggesting that mechanisms for enhanced outcomes with the hormone remain inconclusive.

Clinical trials regarding vitamin D supplementation and risk for sepsis severity and mortality are promising although the results are mixed. In a number of RCTs of critically ill adults, vitamin D supplementation was associated with ameliorated outcomes, reduced length of stay, and decreased mortality [195–197]. In contrast, a systematic review in adults found no link between length of stay, duration of mechanical ventilation, or mortality [198]. However, a single dose of 150,000 IU (3.75 mg) vitamin D in 109 children decreased inflammatory markers, dampened cardiovascular organ failure scores, and reduced progression to septic shock [199]. Additionally, a link between high-dose administration of 200,000 and 400,000 IU (5 and 10 mg) of vitamin D<sub>3</sub> and increased plasma 25(OH)D and LL-37 was observed in a group of 30 adult septic shock intensive care unit (ICU) patients [200]. Globally, a clear consensus of whether vitamin D supplementation can improve outcomes and is a modifiable risk factor for sepsis is challenging to discern due to various factors in study design, such as variabilities in sample sizes and heterogenous populations [198,201].

## 12. Conclusion

Since observations of vitamin D signaling in tissues unrelated to calcium and phosphate regulation in the early 2000s, a number of studies have focused on the role of the hormone in immune responses to date. The majority of in vitro studies on the antibacterial properties of vitamin D have focused on the capacity of the hormone to induce expression of antimicrobial peptides, such as CAMP, to promote autophagy as a mechanism for handling intracellular pathogens, and to enhance and regulate transcription of genes encoding pattern recognition receptors and cytokines. Generally speaking, the in vitro data is well supported by in vivo studies, as vitamin D supplementation has been demonstrated to clinically suppress risk of oral health diseases, urinary tract infections, relapse of Crohn's disease, and may be of benefit for COPD and sepsis, all of which are common immune conditions with dysregulated antibacterial activity.

Additional work uncovering the influence of 1,25(OH)<sub>2</sub>D in antibacterial activities of neutrophils, NK, NK T cells, and  $\gamma\delta$  T cells represent future avenues of investigation, as these innate immune cell populations are crucial in the killing of infected cells [113], immediate release of cytokines [202], and interaction with innate and adaptive cells to provide host defense [203]. Moreover, the significance of the sunshine hormone in regulating antibacterial immune function may motivate development of vitamin D analogs that may serve as constituents of combined therapies or even as front-line therapies for treating bacterial, antibiotic-resistant disease.

### 13. Summary points

- 1,25(OH)<sub>2</sub>D signaling affects susceptibility to and severity of bacterial infection via induction of antimicrobial peptides, pattern recognition receptors, and cytokines in innate immune cells.
- Intracellular bacterial infections, such as *M.tb.*, are suppressed via 1,25(OH)<sub>2</sub>D-stimulated autophagy.
- Preclinical and clinical reports strongly suggest an association between circulating 25(OH)D levels and vulnerability to conditions caused by bacterial infections, such as diseases of oral health, urinary tract infections, and Crohn's disease.
- Exploration of vitamin D supplementation as a therapeutic intervention may be clinically and economically important in the treatment of immune conditions of bacterial origin.

## OBJECTIVES

- Discuss epidemiological association between vitamin D insufficiency and viral diseases.
- Consider potential of in vivo 1,25(OH)<sub>2</sub>D supplementation for improved antiviral immunity.
- Present mechanisms of 1,25(OH)<sub>2</sub>D-regulated antiviral immunity.
- Provide an update on recent advances in antiviral immune actions of 1,25(OH)<sub>2</sub>D in COVID-19.

## 1. Introduction

Viral infections pose a major public health challenge with over 40 million deaths worldwide ascribed to human immunodeficiency virus (HIV) infections since the beginning of the epidemic, over 6.5 million deaths due to the global severe acute respiratory syndrome coronavirus 2 (SARS-CoV2) pandemic in the past 3 years, and significant disease burden due to other respiratory tract infections, such as influenza and rhinovirus, and chronic hepatitis and herpes viral infections based on the World Health Organization (WHO) tallies. Vitamin D, a key nutrient/prohormone classically associated with skeletal health, has emerged as a key immunomodulator, and insufficient levels of circulating

vitamin D (serum 25-hydroxyvitamin D, 25(OH)D) have been associated with increased occurrence of viral infections and disease severity.

Vitamin D may directly inhibit viruses through interaction with viral or cellular proteins necessary for infection, replication, or spread of the virus. For example, the biologically active form of vitamin D, 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D) suppresses HCV production in human hepatocytes by inhibiting the expression of apolipoproteins critical for virion assembly and by interfering with the viral nonstructural 3 (NS3) protein during viral assembly [1–6]. 1,25(OH)<sub>2</sub>D-induced autophagy or apoptosis is another mechanism of viral control in several infections such as HCV, HIV-1, rotavirus, and influenza A virus [7–12]. 1,25(OH)<sub>2</sub>D has also been found to inhibit HIV infection by downregulating chemokine receptor 5 (CCR5), which serves as a coreceptor for HIV-1 entry into the target cells [13], and subsequent viral replication in infected PBMC through the induction of phagosome maturation [7,14]. Likewise, 1,25(OH)<sub>2</sub>D-mediated repression of C-type lectin mannose receptor on macrophages has been shown to impair dengue virus infection [15]. 1,25(OH)<sub>2</sub>D mitigates virus-induced vascular endothelial damage during human cytomegalovirus (HCMV)-induced atherosclerosis [16]. Maintenance of barrier integrity at mucosal sites of viral infection is yet another nonimmune antiviral mechanism by vitamin D. 1,25(OH)<sub>2</sub>D signals through VDR to support mucosal barrier integrity [17–20], by possibly suppressing apoptosis through

a These authors contributed equally.

inhibition of NF- $\kappa$ B [21]. Contrarily, vitamin D has also been shown to induce HCMV growth in monocytic cells by altering a more favorable differentiation state [22]. Likewise, in the case of HIV-1 replication, vitamin D signals have been shown to promote viral LTR transactivation in vitro [23]. Viral proteins, in turn, have been shown to modulate the vitamin D status of host cells as a possible escape mechanism in the case of HBV [24] and EBV [25–27]. As opposed to these nonimmunological mechanisms of viral control by vitamin D, which are uniquely dependent on distinct virological parameters such as host cell types and propagative modes for each virus, the primary goal of this chapter is to present the innate and adaptive immune modulatory effects of vitamin D in the context of distinct viral infections.

The innate immune responses constitute the first line of antiviral defense with broad specificity [28–31]. Triggered by engagement and signaling of pattern recognition receptors (PRRs) by pathogen-associated molecular patterns (PAMPs) and danger-associated molecular patterns (DAMPs) in virally infected target cells, the innate antiviral defense mechanisms directly target viral and cellular factors critical for viral propagation. Production of antiviral and proinflammatory cytokines (such as type I and type III interferons, TNF- $\alpha$ , IL-1 $\beta$ ) and chemokines (such as CCL-2/4, CXCL-8/9/10), serves to further activate and recruit additional innate immune cells through induction of numerous interferon-stimulated genes (ISGs), thus amplifying the innate antiviral defenses. The innate immune mediators also recruit and orchestrate an ensuing adaptive immune response, which acts in a pathogen-specific, adaptable manner, to effectively control the infection and develop long-term pathogen-specific memory.

Exerting pleiotropic effects on both innate and adaptive immune cells (such as macrophages, DCs, NK cells, B cells and T cells), vitamin D is implicated in regulating immune responses to bacterial and viral pathogens, cancer as well as in autoimmunity. The role of vitamin D in regulating innate antibacterial immunity is covered in Chapter 94 by Ismailova and White, and Chapter 96 focuses on regulation of adaptive immunity by vitamin D by Hawrylowicz et al. In this chapter, we first discuss epidemiological associations between vitamin D insufficiency and susceptibility to distinct viral infections and disease, followed by empirical and clinical evidence of innate and adaptive immune regulatory functions of vitamin D in the context of viral infections, and a consideration of potentially beneficial effects of vitamin D supplementation in mitigating clinical disease. In the following discussions, vitamin D sufficiency is generally defined as serum concentrations of 25(OH)D between 50 nmol/L (20 ng/mL) and 125 nmol/L (50 ng/mL) [32,33]. The complex virus–host interactions and immune factors that drive disease control or resolution are unique for distinct viruses. Hence, the antiviral immunomodulatory effects

of vitamin D are complex, and both unique virus-specific aspects as well as unifying principles are discussed here.

## 2. Association between vitamin D insufficiency and viral disease in epidemiological and interventional studies

Observational epidemiological and interventional studies provide a direct association between vitamin D insufficiency and susceptibility to several viral diseases such as acquired immunodeficiency syndrome (AIDS), hepatitis, dengue, herpes, respiratory diseases caused by influenza virus, respiratory syncytial virus (RSV), rhinovirus, and more recently coronavirus-induced disease 2019 (COVID-19), rotaviral gastrointestinal disease, and papillomavirus-induced genital warts and cervical cancer.

### 2.1 Acquired immunodeficiency syndrome

AIDS is caused by a lentivirus, human immunodeficiency virus (HIV), which is a single-stranded, positive-sense, enveloped RNA virus [34]. Poor vitamin D status (as assessed by serum levels of 25(OH)D or 1,25(OH) $_2$ D) is prevalent in HIV-infected patients and is associated with increased AIDS severity and risk of morbidity and short-term mortality [35–40]. Vitamin D insufficiency is associated with significantly higher viral loads in HIV/Kaposi's sarcoma patients, and reduced responsiveness to antiretroviral therapy [41,42]. Consistent with this, HIV-1-exposed seronegative individuals with natural resistance to HIV-1 infection exhibited high levels of 25(OH)D and its receptor (vitamin D receptor, VDR) [43]. Several VDR gene polymorphisms have also been associated with susceptibility to HIV infection and AIDS pathogenesis [44–46]. Moreover, supplementation with 25(OH)D has been shown in independent studies to significantly decrease viral loads and increase the number of circulating leukocytes including naïve CD4 $^+$  T helper (T $_H$ ) cells [47,48]. However, in contrast to the studies discussed before, there are reports of no association between 25(OH)D levels and disease complications [49] or antiretroviral therapeutic outcomes in HIV patients [50]. Likewise, three independent studies noted no significant changes in HIV viral loads, T cell counts, or mortality after supplementation with 25(OH)D or 1,25(OH) $_2$ D in HIV patients [51–54].

### 2.2 Viral hepatitis

Hepatitis C and B viruses are the main etiologic agents of viral hepatitis, an inflammatory liver disease caused by infection of hepatocytes [55,56].

Hepatitis C virus is a hepatotropic, single-stranded RNA virus, which causes inflammation that typically

progresses to liver cirrhosis and hepatocellular carcinoma (HCC) in case of chronic infection [55]. Vitamin D insufficiency (plasma 25(OH)D levels <20 ng/mL) is common among HCV patients, and an inverse correlation between vitamin D levels, viral loads, liver inflammation, fibrosis and cirrhosis hepatic encephalopathy, mortality rate, and progression to hepatocellular carcinoma have been noted in HCV patients [57–63]. Moreover, vitamin D insufficiency (25(OH)D) is associated with decreased response rate to older standard of care antiviral therapy (IFN- $\alpha$ +ribavirin) [57,64–69]. It is unclear whether lower vitamin D levels are a consequence of damaged livers or play a causal role in viral control. In contrast, supplementation with 25(OH)D has been shown to decrease liver fibrosis and increase sustained virological response (SVR) rate to antiviral therapy (IFN- $\alpha$ +ribavirin) [64,65,68,70–73]. Polymorphism of several vitamin D-related genes, such as VDR, vitamin D binding protein (DBP), cytochrome P450 family 24 subfamily A member 1 (CYP24A1) responsible for 24-hydroxylase enzymatic activity, and the 25-hydroxylase enzyme cytochrome P450 2R1 (CYP2R1), is implicated in HCV disease pathogenesis [74–76]. However, some studies have shown no effect of vitamin D insufficiency (circulating 25(OH)D) on viral growth, liver disease, SVR, or supplementation [77–85].

Hepatitis B virus, an enveloped DNA virus, also causes hepatitis. Acute hepatitis related to HBV infection can lead to liver failure and death, whereas viral chronicity is associated with long-term complications such as liver cirrhosis, hepatocellular carcinoma, and high rates of morbidity and mortality [56]. As in the case of HCV patients, epidemiological studies show significantly lower levels of circulating 25(OH)D in chronic HBV patients, with increased HBV DNA loads, decreased seroclearance, and clinical progression of liver cirrhosis outcomes [86–88]. SVR to telbivudine antiviral therapy was also decreased in patients with vitamin D insufficiency [89]. Consistent with this, transgenic murine model of HBV infection showed improved SVR to IFN- $\alpha$  therapy in combination with 25(OH)D supplementation [90]. VDR gene polymorphisms are also associated with distinct disease outcomes, and responses to IFN- $\alpha$  treatment [91–98]. However, several studies also reported contradictory results regarding the effects of vitamin D on HBV infection with no evident association between HBV DNA and serum 25(OH)D levels, liver inflammation, fibrosis, or treatment outcomes with tenofovir plus IFN- $\alpha$  combination therapy [89,99–102].

### 2.3 Herpes

Herpes is caused by human alphaherpesvirus 1 and human alphaherpesvirus 2, double-stranded DNA viruses, which typically remain latent in neurons, but

may undergo occasional reactivation to cause herpetic lesions in mouth, lips, nose, or genitals [103]. A significant association between low serum 25(OH)D levels and the presence of recurrent herpes labialis has been reported [104]. Treatment with 25(OH)D and 1,25(OH)<sub>2</sub>D inhibits HSV-1 growth in HeLa cells infected with HSV-1 [105]. Likewise, a recent report of amelioration of herpes simplex virus-induced Behçet's disease-like inflammation in mice by 1,25(OH)<sub>2</sub>D through downregulation of Toll-like receptors also argues in favor of beneficial effects of vitamin D signals during intracellular infections [106].

### 2.4 Human cytomegalovirus

HCMV, a beta-herpes double-stranded DNA virus (also referred to as human herpes virus 5, HHV5), has widespread seroprevalence worldwide [107,108]. While largely asymptomatic in immunocompetent hosts, acute HCMV infection causes significant morbidity and mortality in immune compromised individuals such as transplant recipients due to lytic viral replication and immune pathology. Lifelong viral persistence in normal hosts is associated with chronic inflammation and chronic allograft rejection. Vitamin D insufficiency has been associated with increased incidence of HCMV disease in infected individuals and increased opportunistic infections with HCMV in kidney transplant recipients [109–111]. However, in apparent contradiction, treatment with 1,25(OH)<sub>2</sub>D failed to inhibit HCMV replication in human foreskin fibroblasts infected with CMV possibly because of VDR downregulation postinfection [112].

### 2.5 Mononucleosis

Epstein–Barr virus (EBV), also known as human herpesvirus 4 (HHV4), a double-stranded DNA virus, is one of the most common human viruses that largely remains latent and causes symptoms mostly in immunocompromised situations [113]. Vitamin D insufficiency is associated with infectious mononucleosis and EBV infection [114].

### 2.6 Dengue fever

Dengue virus, a mosquito-borne, single positive-stranded RNA virus, causes dengue fever [115]. In the case of dengue infections, VDR gene polymorphisms have been identified as predictors of hemorrhagic fever and shock [116], and effects of 1,25(OH)<sub>2</sub>D supplementation on viral replication, immune response, and morbidity have been described [117,118]. High-dose vitamin D treatment also decreased dengue virus infection in patient monocyte-derived dendritic cells [119]. However, paradoxically, low serum 25(OH)D concentrations in dengue fever patients reduced the pathological

progress into dengue hemorrhagic fever/dengue shock syndrome, and circulating 25(OH)D was found to be much higher during an acute dengue episode than during disease-free periods [120].

## 2.7 Virus-induced cervical cancer

Human papilloma virus (HPV) is a small double-stranded circular DNA virus. With over 100 different types of HPV, majority of the infections resolve. However, infection with high-risk type HPV (HPV16 and HPV18) is responsible for the development of cervical cancers in women [121]. With very limited epidemiological studies on vitamin D and HPV infections, there is contrasting evidence both in support of an association between vitamin D insufficiency and HPV prevalence in sexually active women, and against any association between vitamin D insufficiency and the development of cervical cancer [122,123].

## 2.8 Viral diarrhea

Rotavirus is a double-stranded RNA virus that causes diarrheal disease [124]. Rotaviral diarrhea has been associated with vitamin D insufficiency [125]. Consistent with this, treatment with 25(OH)D has been shown to decrease rotavirus replication in intestinal enterocytes in vitro, and in vivo supplementation with 25(OH)D in pigs mitigated inflammation and intestinal damage during porcine epidemic diarrhea virus (PEDV) infection [126].

## 2.9 Pulmonary diseases

Several respiratory tract infections (RTI) such as influenza, respiratory syncytial virus (RSV), parainfluenza, adenovirus, rhinovirus, and related hospitalizations are associated with low serum 25(OH)D levels [127–142]. In contrast, higher 25(OH)D levels in the cord serum have been associated with reduced risk of multitriggered and virally induced wheezing in children [138]. A significant association between polymorphism of VDR, DBP, and the monohydroxylase cytochrome P450 3A4 (CYP3A4) and respiratory viral infections has also been observed [143–148]. Nonetheless, it is debated that these associations between vitamin D insufficiency and seasonal influenza incidences [149,150] might be related to decreased humidity and longevity of viral infectivity due to low temperatures than fluctuations in vitamin D [151,152]. Some studies have reported no effect of vitamin D insufficiency on severity of acute bronchiolitis caused by RSV or the burden of influenza virus infection [128,153–155]. Consistent with this, rhinovirus replication in primary human bronchial epithelial cells was unaffected by

1,25(OH)<sub>2</sub>D levels [156]. While several controlled vitamin D supplementation studies have been conducted in respiratory infections, the results were variable with some studies reporting beneficial effects, while others did not observe beneficial effects in influenza, RSV, or rhinovirus infections [157–159]. Some studies even reported increased frequency of infectious pneumonia [160]. Notwithstanding, a systematic review of randomized controlled trials from 1948 to 2009 has found strong evidence supporting beneficial effects of 1,25(OH)<sub>2</sub>D supplementation for treating acute respiratory illness, tuberculosis, and influenza [161].

## 2.10 COVID-19

Coronavirus-induced disease 2019 is caused by a coronavirus, SARS-CoV2, a positive-sense single-stranded RNA virus that has infected over 643M people and claimed over 6.63M lives in the global pandemic over the past 3 years. Several predisposing factors linked to exacerbated respiratory disease severity in COVID-19, such as age, genetic or ethnic backgrounds, geographical location, and preexistent chronic disease conditions [162–165], are also associated with inadequate vitamin D levels [166–170], thus supporting a possible indirect link between vitamin D insufficiency and COVID-19 severity [164,165,171,172]. There are several review articles that have discussed this concept [173–176].

Cursory cross-sectional global analyses have uncovered higher COVID-19-related mortality in countries with lower average vitamin D status [177]. In several retrospective studies, low levels of 25(OH)D were associated with increased infection, respiratory disease severity, or mortality in SARS-CoV2 infected patients in Sicilian, African American, Swiss, Iranian, and Saudi Arabian patients [178–182]. In a recent retrospective chart review analysis, patients aged  $\geq 65$  years showed a statistically significant association of vitamin D sufficiency with decreased odds of death, acute respiratory distress, and severe sepsis/septic shock, after adjustment for potential confounders [183]. Elderly COVID-19 patients also show increased pulmonary complications, longer sickness, and increased risk of mortality with vitamin D insufficiency compared with age-matched control subjects [184]. Likewise, significantly lower 25(OH)D levels were noted in severely symptomatic COVID-19 patients and were associated with prolonged mechanical ventilation, worse health evaluation score, COVID-19-induced acute respiratory distress syndrome (ARDS), and higher mortality [185,186]. A recent metaanalysis of multiple retrospective and prospective cohort, cross-sectional, case-control, and randomized controlled trial studies (up to November 26, 2020) investigating the relationship

between vitamin D status and SARS-CoV2 incidence or COVID-19 disease severity found a higher risk of SARS-CoV2 infection and COVID-19 severity in groups with compromised vitamin D status in studies that were adjusted and nonadjusted for confounders [163,187–189]. Studies with crude overall response (OR) and the adjusted Cox survival method also revealed a significant inverse association of mortality with 25(OH)D levels in Kazemi et al. [187] and another metaanalysis of studies from Europe and Asia [190]. Another metaanalysis found a trend, albeit statistically insignificant, toward inverse correlation between serum 25(OH)D levels and risk of mortality, ICU admission, and ventilation [191].

Studies of high-dose oral 25(OH)D supplementation (60,000 IU per day for at least 7 days) in SARS-CoV2 infections showed significantly lower rates of ICU admission and enhanced viral clearance and inflammation in a random controlled trial in India [192]. Three distinct British, Greek, and Italian studies of 25(OH)D supplementation in COVID-19 patients also showed significantly reduced risk of mortality [193–195]. However, a multicenter, double-blind, randomized, placebo-controlled trial in Brazil did not find beneficial effects of 25(OH)D supplementation (one dose of 200,000 IU) on the duration of hospital stay or need for mechanical ventilation, compared with the placebo control group [196]. The differences in these studies could be ascribed to differences in timing and dosage of supplementation and patient demographics.

Overall, these epidemiological and interventional studies support a beneficial role of vitamin D supplementation against a variety of viral infections as well as COVID-19, particularly in the elderly, African Americans, and those with low vitamin D status. Nonetheless, contradictory data also abound for most viral infections [197]. This may be ascribed to differences in baseline levels of vitamin D, methods of assessment of vitamin D status, patient demographics, genetics, sample size, seasonal variations, timing and form of vitamin D supplementation (no universal consensus on biologically relevant doses of vitamin D for use in randomized controlled trials), and questionable effectiveness of supplementation [198] due to variation in the method of assay of serum 25(OH)D levels. Moreover, unique modes of viral replication, pathogenesis, and immune control may be impacted differentially by vitamin D signals in distinct infections. In the following sections, we will review the distinct virus-specific mechanisms by which vitamin D regulates disease outcomes in various infections and garner unifying principles of vitamin D regulation of antiviral immunity. The topic of vitamin D and COVID-19 is discussed in greater detail in Chapter 99.

### 3. Immunological mechanisms of viral control

Protective antiviral immune responses comprise concerted actions of the innate and adaptive arms of the immune system [29–31] (Fig. 95.1). As the first line of defense, the broadly reactive innate immune system is triggered by conserved pathogen-associated molecular motifs referred to as PAMPs and DAMPs released by infected target cells through PRRs. TLR signaling then leads to induction of antimicrobial peptides (AMPs). Activation of the innate immune system also results in induction of molecular mediators that directly counter viral growth by targeting key viral and cellular proteins. In addition, inflammatory antiviral cytokines and chemokines produced by innate immune cells serve to further amplify the immune response by recruiting additional innate and adaptive immune cells to the sites of infection. In case the innate immune system is ineffectual at controlling the pathogen, activation and expansion of pathogen-specific lymphocytes represents a targeted counterattack, where T cell and B cell clones against multiple pathogen-specific epitopes mount virus-specific humoral (antibody) and cellular (T cell) responses to eliminate the virus and virally infected target cells. In addition to adapting toward a higher affinity of interaction with viral epitopes, the adaptive immune system is also characterized by the ability to establish a long-lived immune memory compartment after clearance of the primary infection. Immune memory reacts more rapidly and vigorously to a pathogenic rechallenge, thus imparting protection from future reinfection. However, in certain cases of chronic viral infections where the virus persists (such as HIV, HCV), long-lived antigen-independent protective memory does not form, and T cells remain in a functionally repressed state of “exhaustion” [199].

### 4. Vitamin D and immunomodulation

The concept that vitamin D might exert immunomodulatory effects was first seeded about four decades ago by extrarenal production of bioactive vitamin D (1,25(OH)<sub>2</sub>D) by monocytes/macrophages [200–203]. This concept is further supported by findings of VDR and/or enzyme 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase (1 $\alpha$ -hydroxylase) cytochrome P450 family 27 subfamily B member 1 (CYP27B1) expression by other immune cells such as T cells and B cells [166,204–207]. Vitamin D mediates its immunomodulatory effects through its bioactive form, 1,25(OH)<sub>2</sub>D, which binds to the vitamin D receptor (VDR), a nuclear receptor, thus leading to its dimerization with an isoform of the retinoid X receptor (RXR). The VDR-RXR heterodimers then activate transcription of genes by binding to vitamin D response

Created with BioRender.com

**FIGURE 95.1 Overall schematic of immune network of cellular and molecular mediators involved in antiviral immunity.** Antiviral immune responses are typically triggered by innate sensing of pathogen-associated molecular patterns (PAMPs) by pattern recognition receptors (PRRs) such as RIG-I like receptors (RLRs), Toll-like receptors (TLRs), and NOD-like receptors (NLRs), which induce production of antimicrobial peptides (AMP), antiviral cytokines such as interferon- $\alpha$  (IFN- $\alpha$ ), and other proinflammatory cytokines such as IL-1 $\beta$ . Priming of CD4 and CD8 T cells by dendritic cells (DCs) leads to effector T cell responses, which include production of antiviral cytokines such as interferon- $\gamma$  (IFN- $\gamma$ ) and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), as well as target cell killing through effector molecule perforin (Pfn) and serine protease granzyme B (GzmB). Natural killer cells (NKs) also mediate killing of infected target cells through GzmB and Pfn. Priming of B cells also leads to production of virus-specific antibodies, which mediate viral neutralization and antibody-dependent cell cytotoxicity (ADCC) of infected cells.

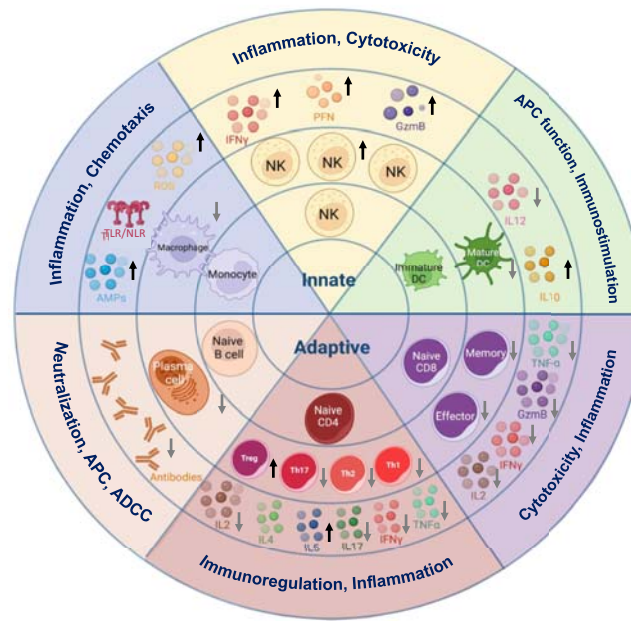

elements (VDREs) in the promoter regions or suppress gene transcription driven by nuclear factor of activated T cells (NFAT) by displacing it from the promoter regions [166,208–211]. Local production of 1,25(OH) $_2$ D by CYP27B1 in immune cells and sensing by VDR expressed on immune cells is proposed to modulate immune function in a paracrine and/or autocrine manner. Immunological outcomes of vitamin D signaling and downstream gene regulation include alterations in a variety of innate and adaptive immune functions (Fig. 95.2), such as regulation of monocyte/macrophage activation [212], induction of autophagy and apoptosis [213–215], increased production of AMPs [216–219], inhibition of inflammation [220–225], regulation of DC maturation, function, and antigen presentation [226–236], inhibition of B cell function [237–240], modulation of T cell trafficking, expansion, and effector functions, and induction of immune regulatory functions [241–250]. In the following sections, we discuss how these immune cells and processes are regulated by vitamin D in the context of viral infections potentially

impacted by host vitamin D status (see Section 3 of this chapter).

## 5. Innate immune sensing of viruses and 1,25(OH) $_2$ D

Toll-like receptors (TLRs) and retinoic acid-inducible gene 1 (RIG-I)-like receptors (RLR) are PRRs, which trigger innate immune responses to viral infections through recognition of PAMPs in viral proteins and nucleic acids [29,251–253]. For example, endosomal TLR3 and TLR7, or cytosolic sensors retinoic acid-inducible gene 1 (RIG-I) and melanoma differentiation-associated gene 5 (MDA5) PRRs are implicated in triggering an innate immune response to SARS-CoV2 viral RNA [254]. Notably, double-stranded RNA, one of the key nucleic acid PAMPs from viral genomes has been shown to increase the expression of CYP27B1 in primary human lung epithelial cells, thus suggesting that PRR signals may upregulate vitamin D signaling [255].

**FIGURE 95.2** Overview of immunomodulatory effects of 1,25(OH)<sub>2</sub>D on components of the innate and adaptive immune systems, typically involved in antiviral immunity. The physiologic outcomes are indicated by arrows indicating increase or decrease in the levels or functions of molecular and cellular mediators of immunity.

TLR1/TLR2 signaling in macrophages enhances CYP27B1 and VDR expression, thus resulting in an increase in localized levels of bioactive vitamin D [256]. In turn, vitamin D signals have been shown to modulate TLR4 signaling through regulation of CD-14 coreceptor expression [257,258]. In HIV-1 infection, TLR8 signals have been shown to inhibit viral growth in human macrophages through induction of VDR, CYP27B1, AMPs, and autophagy [259]. Furthermore, 25(OH)D or 1,25(OH)<sub>2</sub>D supplementation of HeLa cells was shown to significantly downregulate HSV-1 titers, albeit alongside downregulation of TLR2 and TLR9 mRNA levels, possibly due to postsignaling receptor downregulation [105]. Together, these data support the notion that PRR signaling by viral motifs may trigger the vitamin D pathway in infected target cells; vitamin D signals in turn might regulate PRR signaling, while contributing to viral control by augmenting production of AMPs and potentially blocking cellular processes that support viral growth.

## 6. Antimicrobial peptides in antiviral immunity and 1,25(OH)<sub>2</sub>D

AMPs or host defense peptides (HDPs) are molecular effectors of the innate immune response that exert potent, broad-spectrum antimicrobial functions against bacteria, enveloped viruses, fungi, and even cancer cells

through membrane perturbation, blocking of viral entry into host cells, enhanced activation of PRRs through viral proteins and nucleic acids, induction of inflammatory cytokine production, chemoattraction, or production of reactive oxygen species [28,260–266]. Produced by both immune cells (neutrophils, monocytes, NK cells, T cells and B cells [267]) and somatic cells (epithelial cells in the eye, respiratory tract, digestive tract, intestines, urinary tract, and skin) [218,268–270]), AMPs are secreted into the blood. AMPs are also released at the site of viral infection and immune function, where they may also exert chemotactic function to attract neutrophils, monocytes, and lymphocytes [31,271]. In the case of a bacterial respiratory infection, *Pseudomonas aeruginosa*, AMPs have been shown to promote pathogen clearance by inducing apoptosis of infected airway epithelial cells [272]. AMPs have also been shown to activate airway epithelial cells by transactivation of the epidermal growth factor receptor, thus offering potential new mechanisms of action for control of respiratory viral infections [273].

Vitamin D and CYP27B1 have been shown to induce the expression of AMPs such as human beta defensin 2 (HBD2) and cathelicidin [216,217,274,275]. In fact, in the absence of 1,25(OH)<sub>2</sub>D, VDR, or CYP27B1, macrophages and keratinocytes produce minimal cathelicidin [257]. Antiviral effects of AMPs, HBDs, and cathelicidin (or LL-37, the bioactive form of cathelicidin AMP) are well documented against influenza, HIV-1, HSV-1,

HPV, RSV, adenovirus, vaccinia virus, rhinovirus, and HCV [7,269,276–287]. In mouse model of influenza A infection, cathelicidin decreased viral replication and disease severity [288]. In the case of HIV-1, LL-37 inhibited viral reverse transcriptase activity [289]. Additionally, vitamin D–induced AMPs are proposed to be critical for natural resistance to HIV-1 based on positive correlation of elevated levels of VDR, cathelicidin, and human alpha defensin 4 (HAD-4) mRNA in PBMCs and oral mucosa of HIV-1-exposed seronegative individuals [43,290,291]. LL-37 also inhibits HSV-1 corneal infection by blocking virus binding to target host cells [292]. LL37, which is induced by vitamin D signals, has been shown to attenuate HCV infection and has been proposed for combination treatment with the traditional anti-IFN therapy [293]. Likewise, 1,25(OH)<sub>2</sub>D has been shown to attenuate rhinovirus [282,284,294,295] and rotavirus infection by expression of cathelicidin [8]. High concentrations of 1,25(OH)<sub>2</sub>D also increased AMPs in dengue viral infection [296]. Moreover, LL-37 and human  $\beta$ -defensin-2 (hBD2) were recently shown to bind directly to SARS-CoV-2 Spike protein, thus blocking binding to its receptor ACE2, and inhibiting viral entry [266,297]. Thus, vitamin D may enhance viral control through induction of AMPs, which block various stages of viral growth such as receptor binding, target cell entry, genomic amplification, viral enzymatic activity, and virion stability through protein–protein interaction and membrane destabilization.

## 7. Antiviral cytokine and chemokine responses and 1,25(OH)<sub>2</sub>D

PRR signaling typically culminates in activation of IRF-3 and IRF-7 transcription factors that induce production of type I interferons and numerous interferon-stimulated genes (ISGs). Other transcription factors, such as AP-1 family members, and NF- $\kappa$ B also participate in cytokine production during viral infections [28,251,298,299]. In addition to direct antiviral functions, inflammatory cytokines serve to amplify the antiviral immune responses by activating immune cells and promoting their migration, expansion, and effector functions at the sites of pathogen growth. However, overexuberant and/or prolonged inflammation may lead to immunopathology in healthy tissues. For example, excessive inflammation in the lung causes significant pulmonary damage [295], and aberrant inflammation is a lead cause of exacerbated lung disease in tuberculosis (TB) and flu [300]. In the highly pathogenic 1918 influenza A pandemic, pulmonary pathology and fatal outcome were associated with accelerated activation of proinflammatory genes that remained unabated until death [301–303]. Even in SARS-CoV2, increased

inflammation is the key underlying morbidity/mortality [174,304–308].

In general, inadequate vitamin D signals are associated with significantly higher inflammation in viral, bacterial, and autoimmune disorders [232,249,309,310]. In six of seven random control trials of vitamin D in highly inflammatory conditions (such as acute infantile congestive heart failure, multiple sclerosis, inflammatory bowel disease, cystic fibrosis, systemic lupus erythematosus [SLE], active TB, and evolving myocardial infarction), significant antiinflammatory effects were reported [311]. In the context of viral infections, inflammation and 25(OH)D levels were inversely related in influenza and COVID-19 patients as assessed by inverse association between disease severity and CRP levels, IL-6, and IFN- $\gamma$ , as well as a reciprocal relationship with T<sub>H1</sub> genes [185,304,312–314]. Nonetheless, a recent multicenter, double-blind, placebo-controlled, randomized clinical trial did not show improvements in inflammatory cytokines such as IL-12, IL-17, IFN- $\gamma$ , granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-8, interferon-inducible protein-10 (IP-10), macrophage inflammatory protein-1 *beta* (MIP-1 $\beta$ ), monocyte chemoattractant protein-1 (MCP-1), or growth factor vascular endothelial (VEGF) in hospitalized patients with moderate to severe COVID-19 compared with placebo following a single dose of 200,000 IU vitamin D<sub>3</sub> [315].

Largely, anti-inflammatory effects of vitamin D are noted in influenza infection. Administration of high-dose 1,25(OH)<sub>2</sub>D in mouse model of influenza virus infection reduced viral replication as well as inflammatory cytokines, IL-5, IL-6, IL-8, TNF- $\alpha$ , and IFN- $\gamma$  [316]. In addition, latent HIV-1 reactivation is also inhibited by vitamin D through reduction of TNF- $\alpha$  [317]. Likewise, in RSV infection, 1,25(OH)<sub>2</sub>D reduced the expression of NF- $\kappa$ B- and STAT1-driven proinflammatory gene expression programs [137,318]. In rotavirus infection as well, 1,25(OH)<sub>2</sub>D exerted an immunosuppressive role through the miRNA-155-5p-mediated regulation of IRF3 signaling [319]. In the case of dengue virus infection, concentration-dependent immunomodulatory effects of 1,25(OH)<sub>2</sub>D were seen in *in vitro*–infected cells, with immunostimulatory effects of higher concentrations on both proinflammatory (interferon stimulated gene 15, ISG15 and IL-12p70) and anti-inflammatory cytokines (IL-10), and immunosuppressive effects at lower concentrations [15,296,320]. The TLR4/NF- $\kappa$ B/miR-155–5p/suppressor of cytokine signaling (SOCS)–1 axis is involved in this process [321]. Whether physiologic levels of bioactive vitamin D in anatomic micro-niches induce proinflammatory or antiinflammatory immune responses in dengue virus infection remains to be determined.

In contrast, vitamin D largely induced proinflammatory responses in HCV infection by enhancing the IFN

signaling pathway, STAT-1-mediated IFN- $\alpha$  production, and downregulating the TGF- $\beta$ 1/small mothers against decapentaplegic 3 (SMAD3) signaling axis [1,6,322,323]. The inflammatory chemokines/receptors regulated by 1,25(OH)<sub>2</sub>D include RANTES in influenza infection [316] and CCR5 in HIV-1 infection [13]. In contrast, CXCL8 and CXCL-10 are induced by 1,25(OH)<sub>2</sub>D in rhinovirus infection [156]. These complex disease-specific and dose-dependent effects of vitamin D on inflammation in distinct viral infection contexts may be interpreted as a largely balancing act to drive adequate inflammation and downstream immune response (such as lymphocyte activation, expansion, and effector differentiation) for achieving efficacious viral control, while mitigating deleterious immune pathology.

## 8. Natural killer cell responses and 1,25(OH)<sub>2</sub>D

Natural killer (NK) cells play an important role in innate immune responses against viral infections such as influenza A, HIV, and HCV. NK cells mediate direct cytotoxicity against virally infected target cells by recognizing and responding to virus-induced MHC-I downregulation or alterations in activating and inhibitory signals on infected host cells [324,325]. NK cells also promote target cell clearance and modulate adaptive immune responses through production of effector cytokines such as IFN- $\gamma$  and TNF- $\alpha$ , and through antibody-dependent cell cytotoxicity ADCC [324,325].

Vitamin D largely exerts a stimulatory role in NK cell responses, as suggested by increased NK cell degranulation and cytotoxic function in vitro through increased expression of effector molecules such as IFN- $\gamma$ , granzymes A and B, and degranulation marker lysosomal-associated membrane protein-1 (LAMP-1 or CD107a) [326–331]. In vivo as well, direct associations between NK cell function and 1,25-(OH)<sub>2</sub>D levels have been reported [332–334], albeit some studies did not find a clear association [335,336], or even suggested an immunoregulatory role of vitamin D in NK cells [337,338]. In the context of viral diseases, particularly COVID-19, several studies have demonstrated an inverse association between 25(OH)D and NK cell numbers and function [339–342]. These discrepancies may be related to the altered immunologic factors during viral disease, which are not recapitulated in in vitro systems. With such limited datasets, it is imperative that further studies correlating vitamin D levels and NK cell quantity and function in patients infected with different viruses and cause–effect studies in preclinical disease models are conducted to garner better insight into vitamin D–dependent mechanisms of viral control through modulation of NK cells.

## 9. Antiviral CD4 T cell immunity and 1,25(OH)<sub>2</sub>D

CD4 T cells contribute to antiviral immunity by mediating direct cytotoxicity [343], and by producing antiviral and immunomodulatory cytokines, which further regulate CD8 and CD4 T cell effector responses as well as B cell responses [344]. CD4 T cell responses are initiated by presentation of cognate antigen in the context of MHC-II (signal 1), along with costimulatory (signal 2) and cytokine signals (signal 3) by APCs (primarily DCs), leading to clonal expansion and effector differentiation (Fig. 95.3). CD4 T cells differentiate into distinct subsets of effector lineages with unique functions depending on contextual cytokine signals during activation [345]. Antigenic stimulation of naïve CD4 T cells in the presence of IL-2, IL-12, and IFN- $\gamma$  drives the differentiation of proinflammatory T helper subset 1 (T<sub>H1</sub>) cells for efficacious defense against intracellular pathogens. Combination of IL-6, IL-21, IL-23, and TGF- $\beta$  cytokine signals drives the development of proinflammatory T helper 17 (T<sub>H17</sub>) T cells, also important in antiviral immunity [345,346]. IL-6 and IL-21 along with costimulatory ICOS signals and TCR signals, drive T follicular helper (TF<sub>H</sub>) cells, which help counter viruses by promoting virus-specific B cell immunity through B cell activation and antibody affinity maturation. A subset of CD4 T cells, regulatory T cells (Treg), which are stimulated by antigen, IL-2 and TGF- $\beta$  cytokines, and CD28 costimulatory signals, plays a crucial role in antiviral immunity by regulating T cell priming and effector functions of both CD4 and CD8 effector T cells [345].

Both CD4 and CD8 T cells express VDR and Cyp27B1, which is upregulated upon T cell activation [166,199], thus supporting the notion that T cells can respond to and produce bioactive vitamin D signals [347]. 1,25(OH)<sub>2</sub>D inhibits CD4 T cell activation and proliferation [348–350], possibly through repression of IL-2 [351]. 1,25(OH)<sub>2</sub>D signals interface with MAPK/Erk signaling pathway in many immune cell types and may regulate T cell activation and proliferation by modulating MAPK signaling [352–357]. In nonviral systems, trafficking of T<sub>H</sub> cells to tissue sites is regulated by vitamin D [246]. Additionally, 1,25(OH)<sub>2</sub>D increases proportions of Treg cells and reduces T<sub>H1</sub> and T<sub>H17</sub> cells [244,358–360]. Consistent with suppression of T<sub>H1</sub> differentiation by vitamin D, VDR expression is reduced on T<sub>H1</sub> cells [242]. Proinflammatory cytokines produced by T cells, such as IFN- $\gamma$ , TNF- $\alpha$ , and IL-2, induce Cyp27b1 expression [200,361–363], thus suggesting a possible negative feedback loop for regulating T cell responses.

Importantly, in the context of viral infections, 1,25(OH)<sub>2</sub>D treatment has been shown to reduce HIV-1

**FIGURE 95.3 Regulation of antiviral T cell immunity by 1,25(OH)<sub>2</sub>D.** Antiviral T cell responses in conditions of suboptimal (– Vitamin D; peach box) or increased (+ Vitamin D; teal box) vitamin D signals are presented. Increased maturation (as indicated by increased expression of MHC (signal 1), costimulatory molecules (signal 2), and inflammatory cytokines (signals 3) of antigen-presenting cells (APCs) is proposed to lead to increased activation and effector T cell responses under vitamin D insufficiency/deficiency conditions, while also inducing inflammation and immunopathology. On the other hand, vitamin D sufficiency conditions are proposed to moderate APC function, T cell activation, and effector functions in part through reduced production of proinflammatory (signal 3) cytokines, growth cytokine interleukin-2 (IL-2), and increased levels of Treg cells. This leads to regulated inflammation and immunopathology, with slightly impaired killing of virus-infected target cells by cytotoxic T lymphocyte (CTL) activity.

transmission by specifically modulating the activation of T cells [364]. Furthermore, consistent with largely suppressive effects of 25(OH)<sub>2</sub>D supplementation on proinflammatory cytokines such as IL-5 and IFN-γ in influenza A virus and SARS-CoV2 infections [185,304,312,313], expression of VDR and CYP27B1 was associated with transition from proinflammatory interferon-γ<sup>+</sup> T<sub>H</sub>1 cells to suppressive interleukin-10-producing cells upon complement activation [314]. Importantly, patients with severe COVID-19 showed a reciprocal relationship between T<sub>H</sub>1 and vitamin D–repressed gene signatures in bronchoalveolar lavage, thus indicating possible localized immunopathology, and supporting potential clinical benefit from vitamin D supplementation [314].

These immunosuppressive effects of vitamin D on T cells may be a combined result of autocrine and/or paracrine 1,25(OH)<sub>2</sub>D signaling in T cells, or through indirect effects of vitamin D on APCs. 1,25(OH)<sub>2</sub>D directly regulates the maturation and antigen presentation functions of monocytes/macrophages and DCs by downregulating surface expression of MHC class II and costimulatory molecules (such as CD40, CD80, and CD86) [212,365]. Vitamin D further drives differentiation of tolerogenic DCs with reduced IL-12 and TNF-α production and increased production of antiinflammatory IL-10, thus leading to preferential differentiation of Treg cells than inflammatory T<sub>H</sub> subsets [226–235,366,367]. These findings support a model of vitamin D–dependent modulation of T<sub>H</sub> fate

determination through alterations in the maturation and function of APCs. Further confirmations of vitamin D-dependent *in vivo* induction of tolerogenic DCs and skewing of T<sub>H</sub> responses in favor of Treg cells and against inflammatory T<sub>H1</sub> and T<sub>H17</sub> cells in multiple viral infections would solidify a universal role of vitamin D in regulating inflammatory antiviral T<sub>H</sub> cell responses through DC modulation.

## 10. Antiviral CD8 T cell immunity and 1,25(OH)<sub>2</sub>D

CD8 T cell immunity plays a crucial role in the control of viral infections including HIV-1, dengue virus, HBV, HCV, HSV, etc. [166,199]. CD8 T cells mount an antigen-specific response against virally infected target cells, which includes targeted killing of infected host cells through induction of apoptosis by perforin and granzyme B cytotoxic mediators or death receptor-mediated killing through Fas. CD8 T cells also produce cytokines, which exert antiviral effects, and/or immunomodulatory functions [28,368,369]. Naïve antigen-specific CD8 T cells are stimulated through the T cell receptor (TCR) by cognate peptide–MHC-I complexes on APCs in the secondary lymphoid organs. Costimulatory signals through CD28 are a necessary second signal for optimal activation [368,370]. Inflammatory cytokines, such as IL-12 and type-I interferons, serve as third signals for optimal expansion and effector differentiation of naïve CD8 T cells into cytotoxic T lymphocytes (CTLs) [370–376]. Fully differentiated effector T cells downregulate the expression of L-selectin and C–C chemokine receptor type 7 (CCR-7) and acquire the ability to migrate out of the lymph nodes, into peripheral sites of infection where they mediate effector functions such as specific lysis of infected targets and cytokine production.

As opposed to clear antiproliferative functions of vitamin D in CD4 T cells, 1,25(OH)<sub>2</sub>D has varying effects on CTL proliferation depending on the stimulation used [377–379]. With respect to effector CTL function, a study reported that pretreatment with 1,25(OH)<sub>2</sub>D compromises target cell lysis as assessed by Cr<sup>51</sup> release assay in the setting of an *in vitro* mixed lymphocyte reaction [380]. *In vitro* stimulation of CD8 T cells in the presence of higher concentrations of 1,25(OH)<sub>2</sub>D leads to reduced IL-2 and IL-17 [166,246,379,381,382]. Suppression of IL-2 (a key T cell growth factor) by 1,25(OH)<sub>2</sub>D is proposed as a potential mechanism for inhibiting T cell proliferation [351]. CD200, an immunoglobulin-like molecule that dampens proinflammatory activity of innate cells, is upregulated in human peripheral and airway resident CD8 T cells in response to 1,25(OH)<sub>2</sub>D [383].

In the context of human disease, 1,25(OH)<sub>2</sub>D has been shown to suppress production of effector cytokines (IFN- $\gamma$  and TNF- $\alpha$ ) by EBV-specific CD8 T cells, but enhance production of IL-5 and transforming growth factor (TGF)- $\beta$  in *in vitro* cytokine production assays [384]. In the well-established murine model of acute infection with lymphocytic choriomeningitis virus (LCMV), which is widely used to study antiviral effector and memory CD8 T cell responses, and was originally employed to establish the key immunological concept of MHC-I restriction of CD8 T cell responses [385,386], VDR deficiency was associated with increased CTL expansion, compromised effector differentiation and survival, dysregulated CTL homing, and development of a less diverse virus-specific CTL repertoire postactivation [382].

In summary, analogous to immunosuppressive effects in CD4 T cells, the limited data in CD8 T cells support a similar inhibitory role of vitamin D signals in CD8 T cell antiviral responses with respect to antigen-specific clonal expansion, effector CTL differentiation, diversity of effector and memory repertoire, and modulation of migratory and survival properties. However, how well *in vitro* observations reflect *in vivo* immunological outcomes of autocrine and paracrine vitamin D signals in CD8 T cells the context of diverse viral infections with complex milieu due to unique host–pathogen interactions remain to be fully addressed. In addition, it remains unclear whether vitamin D regulates CD8 T cell responses through direct signaling in CD8 T cells, or indirectly through modulation of APCs (such as DCs, macrophages, B cells). Likewise, the key transcriptional and metabolic mediators of vitamin D-dependent regulation of antiviral T cell immunity also remain to be elucidated.

## 11. B cell responses to viruses and 1,25(OH)<sub>2</sub>D

B cells mount an antiviral response through production of virus-specific antibodies, which serve as effector molecules by neutralizing viral infectivity and through antibody-dependent cell-mediated cytotoxicity (ADCC) [28]. B cells express both VDR and CYP27B1, which are further upregulated upon B cell stimulation through the B cell receptor on the cell surface [240]. Stimulation of naïve B cells through the BCR typically promotes their differentiation into effector plasma cell clones, which secrete high levels of antibodies of a given antigen specificity [369,387,388]. In addition, activated B cells also produce cytokines and participate in antigen presentation to T cells. In *in vitro* studies, 1,25(OH)<sub>2</sub>D inhibits differentiation of B cells into plasma cells and antibody production [237,240,241]. Inverse association between serum 25(OH)D levels and anti-EBNA-1 IgG titers has

been reported prior to clinical MS disease manifestation, and 25(OH)D supplementation significantly reduced anti-EBNA-1 IgG titers [389]. Likewise, EBV-specific memory B cell formation is also inhibited by 25(OH)D [390]. However, another independent study did not find any changes in anti-EBNA-1 IgG titers upon supplementation [391]. On the other extreme, higher vitamin D levels were found to correlate with increased production of influenza virus–specific antibodies [158]. These findings underscore the importance of more in-depth cause–effect type studies on how B cell responses are modulated by vitamin D in the context of distinct viral infections.

## 12. Conclusions

Overall, 1,25(OH)<sub>2</sub>D signaling seems to play a key immune balancing act by promoting viral control through increased innate sensing of viruses, and enhanced production of AMPs and antiviral cytokines, on one hand (Fig. 95.4). On the other hand, 1,25(OH)<sub>2</sub>D suppresses deleterious bystander immunopathology by inhibiting the production of proinflammatory cytokines and chemokines, and enhancing the expression of antiinflammatory cytokines in certain viral infections (such as influenza, SARS-CoV2, and HIV-1). Consistent with this, inflammatory CD4 T<sub>H1</sub> and effector CD8 T cell responses are regulated, whereas regulatory CD4 T cells are enhanced by 1,25(OH)<sub>2</sub>D signaling in certain viral infections. Vitamin D–dependent alterations in immune cell trafficking to sites of viral infection and/or secondary lymphoid sites of immune activation are implied by observations of altered chemokine expression under conditions of varying 1,25(OH)<sub>2</sub>D signaling in viral infections. Nonetheless, our understanding of the

immunomodulatory functions of vitamin D in the context of different viral infections remains incomplete, especially as pertains to NK cell immunity and adaptive virus-specific T and B cell responses.

In general, 1,25(OH)<sub>2</sub>D signaling impairs maturation and antigen-presenting functions of macrophages, DCs, and B cells, thus offering regulation of antigen presentation as a potential mechanism of impaired T cell immunity in virus infections. Direct regulation of activation, expansion, and effector differentiation of virus-specific T cells and B cells by 1,25(OH)<sub>2</sub>D signaling is also implicated in vitamin D–dependent control of adaptive immune responses in viral infections. However, clear establishment of cause–effect relationship between 1,25(OH)<sub>2</sub>D signaling and modulation of antiviral immunity requires systematic and rigorous foundational preclinical studies of diverse viral infections in immunocompetent animal models, with an immunologically targeted enquiry into virus-specific mechanisms of immune control under tightly controlled in vivo conditions of vitamin D sufficiency, insufficiency, deficiency, and supplementation. Since viral infections largely occur through mucosal surfaces, how 1,25(OH)<sub>2</sub>D signaling impacts antiviral immunity at mucosal barriers is an important area of investigation that may be readily conducted in preclinical animal infection models. In parallel with preclinical studies, clinical correlations of vitamin D sufficiency or insufficiency with immune parameters of viral control will guide better informed randomized controlled trials of 1,25(OH)<sub>2</sub>D supplementation with tightly defined patient cohorts (with respect to variables such as age, race, ethnicity, genetics, weight, disease status at the time of enrollment), precise and universally accepted pre- and post-treatment measures of vitamin D metabolites, and virus-specific immune biomarkers of disease control. Collectively, these research findings will bolster generalized efforts of vitamin D supplementation at a population level to better manage viral outbreaks and epidemics in the future.

**FIGURE 95.4 Summary of the immunobalancing role of vitamin D in viral infections.** The existing data supports a model of immunoregulation by 1,25(OH)<sub>2</sub>D, where overall viral control (*green*) is enhanced through induction of innate antiviral immunity (such as production of AMPs and possibly NK cell function), whereas adaptive T cell immunity and proinflammatory immune responses (*red*) are regulated to possibly mitigate bystander immunopathology.

## 13. Summary points

- Preclinical and clinical reports suggest an association between circulating 25(OH)D levels and vulnerability to viral infections and disease severity in disease conditions such as AIDS, COVID-19, influenza, and other viral respiratory diseases, hepatitis, herpes, and viral diarrhea.
- 1,25(OH)<sub>2</sub>D signaling affects susceptibility to and severity of viral diseases via innate sensing of viruses through PRRs, induction of AMPs, and cytokines and chemokines in infected target cells and innate immune cells.

- In most viral infections, such as influenza, HIV, and SARS-CoV2, 1,25(OH)<sub>2</sub>D promotes balanced anti-inflammatory and proinflammatory cytokine responses to balance beneficial antiviral immunity and deleterious immunopathology.
- 1,25(OH)<sub>2</sub>D signaling largely favors regulatory CD4 T cell responses and suppresses inflammatory effector CD8 and CD4 T<sub>H1</sub>-type responses in viral infections through regulation of T cell activation, expansion, effector functions, and by regulating the immunostimulatory capacity of APCs.
- More directed clinical and preclinical studies are needed to build a complete picture of mechanisms underlying vitamin D-dependent regulation of antiviral NK cell, T cell, and B cell responses in distinct viral infections.

## OBJECTIVES

- Describe vitamin D actions on effector and regulatory T cell responses through direct effects on naïve and memory T cells and indirect effects via antigen-presenting cells.
- Review data on modulation of B cell and antibody responses, including responses to vaccination.
- Overview clinical studies of vitamin D status or repletion, where these support in vitro findings and potential explanations for disparities in clinical versus experimental studies.
- Discuss translational studies that support a role for vitamin D in maintaining immune homeostasis at the level of adaptive immunity, highlighting studies in airway disease.

## 1. Introduction

The immune system comprises both innate and adaptive arms. The former represents the first line of defense to pathogens such as bacteria (see [Chapter 94](#)) and viruses (see [Chapter 95](#)), through the actions of physical barriers (e.g., skin, bronchial epithelial cells), soluble

mediators (e.g., mucus, complement), and specialized immune cells (e.g., macrophages, neutrophils). These cells express pathogen recognition receptors (PRRs), such as the Toll-like receptor family (TLRs), which recognize pathogen-associated molecular patterns (PAMPs). Dendritic cells are innate cells that express many PRRs, reside at sites of pathogen entry, and form a crucial link between innate and adaptive immunity in their role as antigen-presenting cells (APCs) (see [Chapter 9](#)). It is therefore difficult to investigate the effects of vitamin D upon adaptive immunity, without also considering the effects upon innate immune cells, such as dendritic cells (see [Chapter 9](#)). Adaptive or acquired immunity is characterized by the generation over time of highly specific, long-lived immune responses that are required for protection against pathogen infection. A key characteristic of adaptive immunity is the capacity to respond more effectively and rapidly to antigens that have been previously encountered, which is termed immune memory and forms the basis of successful vaccination.

The key players of humoral and cell-mediated adaptive immunity are antibody-producing B lymphocytes and T lymphocytes, respectively. The latter contains two major categories, CD4 + and CD8 + T cells, which are further divided into subsets based on function. T and B cells respond not only to pathogens or components of pathogens but also to harmless antigens present

in our environment such as allergens. Inappropriate adaptive immune responses to self-antigens can lead to autoimmune conditions such as rheumatoid arthritis or multiple sclerosis. The failure to mount appropriate adaptive immune responses to tumor cells is also detrimental for the host. Parallel regulatory mechanisms have evolved to limit over-exuberant immune responses to pathogens, prevent damaging or inappropriate adaptive immune responses to self and environmental antigens, and thereby maintain immune homeostasis. Many diseases are characterized by a failure in adaptive regulatory responses, leading to loss of self-tolerance and the failure to control inappropriate immune responses.

The different classes of lymphocytes are programmed to provide finely tailored responses to diverse types of immune challenge. A crucial difference between B and T lymphocyte responses is that B cells directly recognize conformational determinants within antigens by a specific B cell antigen receptor (BCR or immunoglobulin), whereas T cells use their T cell receptor (TCR) to recognize peptide fragments of antigen bound to MHC class I (CD8) or MHC class II (CD4) on the surface of APCs. A commonality is that both the BCR and TCR exhibit immense diversity in their antigen binding sites enabling them to recognize a wide array of antigens.

Epidemiological evidence that links vitamin D status with the incidence and control of a wide range of disease conditions has garnered significant interest in not only whether restoring vitamin D sufficiency can improve health outcomes, but also the immune mechanisms modulated by vitamin D that underpin such effects. Vitamin D has well-documented effects on multiple, functionally divergent, immune effector, and regulatory pathways within the adaptive immune response, which forms the focus of this chapter in the context of human immune homeostasis and disease.

## 2. Epidemiological and other evidence supporting a role of vitamin D in immune disease

Two important lines of evidence support a role for vitamin D in control of adaptive immunity and immune-mediated diseases. Firstly, as covered throughout this series of reviews, many immune-mediated diseases demonstrate striking associations with latitude and/or levels of sun exposure, frequently used as surrogate indicators of vitamin D status, as well as directly with vitamin D status, commonly measured as circulating levels of the vitamin D precursor, 25-hydroxyvitamin D<sub>3</sub> (25(OH)D<sub>3</sub>). Associations with multiple autoimmune conditions include with type 1 diabetes, multiple sclerosis, and inflammatory bowel disease. Associations between vitamin D insufficiency and deficiency and the incidence and severity

of disease have also been described for cardiovascular conditions, allergy, and cancers [1–3]. Associations with the incidence, severity, and treatment response in chronic respiratory disease, reflecting the authors' interests, are also prominent and therefore highlighted throughout this chapter [4,5] (see also Chapter 44).

Secondly, the vitamin D receptor (VDR) is expressed by essentially all immune cells either constitutively or following activation. Enzymes in the metabolic cascade leading to the generation of active vitamin D (1,25-dihydroxyvitamin D<sub>3</sub> or 1,25(OH)<sub>2</sub>D<sub>3</sub>) are expressed in tissues where adaptive immune responses occur, by structural cells such as barrier epithelial cells in the airways, skin keratinocytes, and innate immune cell populations such as dendritic cells and macrophages (see Chapter 9). T cells are dependent for their activation on signals from APCs or accessory cells such as dendritic cells and macrophages. In a two-way process, T cells and their products regulate the function of dendritic cells and macrophages. T cell-derived cytokines such as IL-4 and IFN-γ can modulate not only the antigen-presenting function of these cells, but also the bioavailability of 1,25(OH)<sub>2</sub>D<sub>3</sub> by regulating the expression of crucial enzymes in the metabolic cascade such as 1α-OHase (CYP27B1) and 24-OHase (CYP24A1) [6,7].

## 3. Translational studies as a window to study effects of vitamin D on adaptive immunology

The following sections describe laboratory observations and to a lesser extent reports in animal models of the effects of vitamin D on adaptive immune cell populations. However, to better understand physiologically relevant effects of vitamin D on adaptive immunity, one approach is to investigate how parameters identified to be of interest are linked to vitamin D status (serum levels of 25(OH)D) in patients, and less commonly in healthy individuals. A second approach is to study individuals pre and post-vitamin D supplementation or, rarely, following UVB irradiation. However, clinical study and trial designs have varied widely, making comparisons and clear conclusions challenging. Areas in which such studies vary include 25(OH)D status at the start of the study—which in some cases was unknown, or where participants were not shown to be 25(OH)D deficient/insufficient at the start of the trial. The dose and form of vitamin D (e.g., vitamin D<sub>2</sub> vs. vitamin D<sub>3</sub>), supplementation frequency (e.g., ranging from daily to 2 monthly bolus doses), and duration (a single bolus vs. daily/weekly/monthly delivery over days to months) of administration have all varied between different studies. Recent studies have also shown that serum 25(OH)D<sub>3</sub> levels, the most commonly used measure of vitamin D status, can decrease with inflammatory status (e.g., during acute-phase responses,

sepsis, and with increased bactericidal activity)—possibly suggesting that higher supplementation doses are required in these instances [8]. Furthermore, there is increasing awareness that ethnicity and polymorphisms in genes within the vitamin pathway can impact efficacy of repletion and nature of changes that occur [9]. As discussed in the following, vitamin D sufficiency is likely to promote immune homeostasis through dampening adaptive effector responses and promoting mechanisms of peripheral tolerance, in addition to important effects on innate and structural cells discussed elsewhere. Therefore, maintaining long-term vitamin D sufficiency is likely to be crucial and is an additional and important consideration in the interpretation of human supplementation studies. Examples of where vitamin D-mediated effects on adaptive immunity are mirrored through such translational approaches are highlighted throughout the following sections.

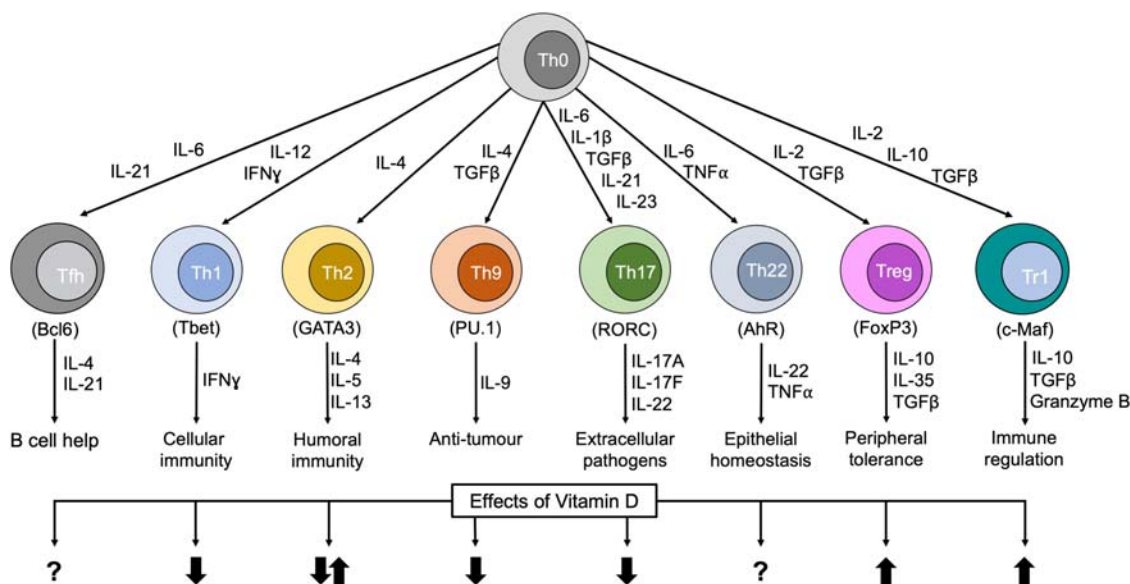

#### 4. Actions of vitamin D on proinflammatory T lymphocyte responses

A pioneering study in 2013 identified thousands of VDR-binding sites in the genome of T lymphocytes, suggesting that vitamin D has the capacity to control gene transcription in these cells [10]. Further studies identified VDR upregulation and expression of CYP27B1, required for conversion of  $25(\text{OH})\text{D}_3$  into  $1,25(\text{OH})_2\text{D}_3$ ,

in both CD4 and CD8 T lymphocytes following activation [11,12]. However, it is unclear what the physiological contribution of endogenous production of active vitamin D by human T cells is, with CD4 + T cells expressing CYP27B1 at comparatively low levels to dendritic cells, and conflicting reports on whether precursor  $25(\text{OH})_2\text{D}_3$  is able [13] or unable [14,15] to alter T lymphocyte responses without APCs also present in different experimental systems. Combined  $1,25(\text{OH})_2\text{D}_3$  from dendritic cells, accessory cells, and structural cells within the local milieu are likely to contribute to immuno-modulatory effects on T cells, as well as autocrine effects following T cell activation (see Chapter 9 for further discussion of local vs. systemic synthesis of  $1,25(\text{OH})_2\text{D}_3$ ).

#### 5. Naïve T cells

Studies on the effects of vitamin D on T lymphocytes have focused on the control of previously activated or memory cells, and effector and regulatory T cell function, with fewer reports of how vitamin D influences naïve T cells. Naïve T cells are critically dependent on dendritic cells for activation and signals that influence their differentiation into functionally distinct subsets (Fig. 96.1). By maintaining dendritic cells in an immature or tolerogenic state, vitamin D is more likely to

**FIGURE 96.1 CD4<sup>+</sup> T helper cell subset differentiation.** Naïve CD4<sup>+</sup> T cells differentiate, upon antigen encounter, into distinct subsets influenced by signals from antigen-presenting cells and the local inflammatory milieu. These subsets are characterized by their master transcription factors (in brackets) and cytokine profiles. Vitamin D has varying effects upon CD4<sup>+</sup> T cell subsets, decreasing Th1 and Th17 responses, while increasing IL-10 expression and Foxp3<sup>+</sup>Tregs, with more complex reports upon Th2 immunity. This is likely to reflect both indirect effects of vitamin D upon antigen-presenting cells and direct effects on T cells. T effector cells exhibit plasticity and can co-express their signature cytokine, such as IFNγ or IL-17A, with other pro-inflammatory cytokines, or anti-inflammatory cytokines such as IL-10 in a process modulated by vitamin D in favor of co-expression of IL-10.

favor naïve T cell maintenance and the generation and maintenance of regulatory T cells.

Naïve T cells express no or low levels of VDR and require activation to increase VDR [16]. In studies in mice, vitamin D was reported to activate naïve CD4+ T cells, albeit following culture in the absence of APCs for 1–3 weeks, to promote a T helper (Th)2 response and upregulate the Th2-associated transcription factors c-Maf and GATA3, while downregulating Th1 responses [17]. A second study suggested 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibited both Th1 and Th2 responses when added at the start of *in vitro* polarization in naïve T cell cultures; however, if cells were first activated and 1,25(OH)<sub>2</sub>D<sub>3</sub> added after 4–7 days of culture, then Th2 responses were no longer reduced [18]. Using human cells, von Essen demonstrated that VDR expression by naïve T cells was induced by TCR signaling via the alternative mitogen-activated protein kinase p38 pathway. TCR signaling via p38 was proposed to drive successive induction of VDR and PLC-γ1, which were required for subsequent classical TCR signaling and T cell activation [16].

## 6. Effects of vitamin D on CD4+ T cell subsets

Specific T cell subsets (e.g., Th1, Th2, Th17; Fig. 96.1) possess specialized roles in protection against diverse pathogens and immune-mediated disease. Vitamin D influences these subsets both directly and indirectly through effects on dendritic cells, including through modulation of the costimulatory molecules expressed by these cells, and via the soluble mediators they produce.

### 6.1 Th1 cells

Th1 cells play a central role in protection against intracellular pathogens (e.g., viruses, bacteria) where the Th1 signature cytokine, IFNγ, enhances antimicrobial functions of macrophages and other innate cells. Th1 cells are also implicated in human disease and can contribute to immune-mediated pathology caused by uncontrolled inflammation and autoimmune conditions. Vitamin D has consistently been observed to decrease the Th1-associated cytokine, IFNγ, and the Th1-associated transcription factor T-bet [14,17,19]. Recent *in vitro* work suggests that a reduction in IFNγ production, and the concomitant upregulation of the anti-inflammatory cytokine IL-10 can be induced in human CD4+ T cells by both the active and precursor forms of vitamin D, suggesting that these cells can both synthesize and respond to 1,25(OH)<sub>2</sub>D<sub>3</sub> due to their ability to express CYP27B1 [13]. In the experimental system studied, complement signaling, via C3b binding to

its receptor CD46 on CD4+ T cells, drives Th1 differentiation followed by their shutdown. The initial production of IFNγ is followed by expression of IFNγ together with IL-10, and subsequently, IL-10 alone [20]. In follow-up mechanistic studies, CD46 was shown to induce expression of VDR and CYP27B1, leading to the shutdown of the Th1 response, and was proposed as an example of an intracrine pathway in T cells [13], with vitamin D driving this transition through epigenetic modifications and transcription factor (BACH2 and STAT3) recruitment. Further to this, Chauss et al. [13] found that bronchoalveolar lavage (BAL) CD4+ T cells from COVID-19 patients were Th1-skewed, with de-repression of genes that are down-regulated by vitamin D – possibly through vitamin D deficiency or pathway dysfunction. In other studies, analysis of the transcriptomic profile of CD4+ T cells upon interaction with autologous vitamin D<sub>3</sub>-induced tolerogenic dendritic cells showed a significant down-regulation of genes involved in the cell cycle and antigen responses, suggesting the induction of an antigen-specific hyporesponsiveness, in combination with a reduction of the Th1 profile [21]. Conversely, vitamin D has been described to be required for many IFNγ-induced antimicrobial pathways in monocytes and macrophages [22].

### 6.2 Th2 cells

Th2 cells provide protective immunity against helminth infection and facilitate tissue repair, but also contribute to chronic inflammatory diseases such as asthma and allergy, where sensitization increases allergen-specific Th2 and IgE responses [23]. The effects of vitamin D on Th2 responses are complex, with differences reported between studies. The inhibition of Th1 responses by vitamin D in culture is often observed with a reciprocal enhancement of Th2 frequency and increase in the Th2-associated cytokines IL-4, IL-5, and IL-13, as a consequence of the increase in transcription factor GATA3 [17,24]. Some recent studies have recapitulated this finding, including in peripheral blood mononuclear cells (PBMCs) isolated from preeclamptic women [25] and in asthma, where a positive correlation between serum vitamin D status and IL-13 synthesis induced in culture was noted [26]. Similarly in a recent study, human healthy skin explants were exposed *in vitro* to the analog of 1,25(OH)<sub>2</sub>D<sub>3</sub>, calcipotriol, and upon co-culture with allogeneic naïve CD4+ T cells drove differentiation toward a Th2 phenotype synthesizing IL-4 and IL-13 [27]. In contrast, active vitamin D is able to inhibit Th2 cytokine secretion in human cord blood cultures [28].

*In vivo* animal models may help our understanding of these seemingly contradictory observations. Intra-

peritoneal administration of  $1,25(\text{OH})_2\text{D}_3$  had anti-inflammatory effects in an *in vivo* mouse model of asthma, which were attributed in part to the control of the integrin-mediated homing of T cells [29]. In an early life model, *in utero* and early-life vitamin D deficiency introduced via feeding with a vitamin D-low chow exhibited enhanced Th2 responses alongside a reduced T cell IL-10 response in mice, a profile that was enhanced by allergen exposure [30]. The capacity of vitamin D to induce or maintain a range of pathways linked to peripheral tolerance, discussed further in the following, may also be important to our understanding how vitamin D controls Th2 responses. At least one pathway may be specific to the control of Th2 responses, in a study in which vitamin D increased expression of the soluble decoy receptor ST2 by human bronchial and nasal epithelial cells and CD4+ T lymphocytes [15].

Notably most, but not all [26], translational or experimental medicine studies do not show evidence for vitamin D treatment inducing an increase in Th2 cytokine production, or more importantly of exacerbating conditions underpinned by Th2-immunity, such as allergic disease or asthma [5,31]. There is also evidence that supplementation can modulate Th2 responses. For example, Nguyen et al. [32] treated seven cystic fibrosis patients with allergic bronchopulmonary aspergillosis with daily cholecalciferol (4000 IU), albeit without a placebo control group, for 24 weeks and measured production of IL-13 by aspergillus-induced dendritic cell-stimulated CD4 lymphocytes before and after. Decreased IL-13 and IgE responses were observed when compared with baseline.

Importantly, observational studies in children indicate an inverse association between vitamin D status and the development of allergy, including food allergy and asthma [31]. Secondary analyses of two clinical trials (VDAART and COPSAC) of high-dose vitamin D supplementation in pregnancy indicate that achieving vitamin D sufficiency throughout pregnancy reduces the incidence of asthma/recurrent wheeze at 3 years [33,34]. A decrease in allergic sensitizations was also observed in the primary analyses in the VDAART study [35]. In an important longitudinal study that monitored vitamin D status over the first decade of life,  $25(\text{OH})\text{D}_3$  deficiency in early childhood was associated with increased risk for persistent asthma. The authors proposed that plausible contributory factors were modulation of susceptibility to early allergic sensitization, together with effects on upper respiratory tract colonization with bacterial pathogens [36].

### 6.3 Th9 cells

IL-9 is the signature cytokine synthesized by Th9 cells that are associated with anti-helminth and anti-tumor immunity. Regulation of mast cell function, IgE

synthesis, mucus production, and eosinophil maturation by Th9 cells implicates them in immune-mediated and allergic pathology [37]. Vitamin D has been shown to inhibit IL-9 synthesis in an IL-10-dependent manner via a mechanism involving the inhibition of basic leucine zipper transcription factor, a transcription factor important for IL-9 synthesis in Th9 cells [38], and the Th9-associated transcription factor PU.1 [39]. Recent data has also shown that  $1,25(\text{OH})_2\text{D}_3$  is able to attenuate TLR2-mediated differentiation of Th9 cells, a mechanism that appears to involve the downregulation of downstream components of TLR2 including IL-33 and its receptor ST2 [40]. The authors demonstrated that reduced levels of  $25(\text{OH})\text{D}_3$  were inversely associated with enhanced IL9 and TLR2 expression as well as disease severity in patients with rheumatoid arthritis.

### 6.4 Th17 cells

Th17 cells are important for protection against pathogens (e.g., fungi, extracellular bacteria) at mucosal sites, but are also linked to a range of inflammatory conditions, including autoimmune disease and chronic airway illnesses such as severe asthma and COPD.  $1,25(\text{OH})_2\text{D}_3$  is consistently observed to inhibit the production of Th17 cytokines both *in vitro* and *ex vivo* [19,41–46] as well as the expression of CCR6, thus preventing their migration to inflamed tissues. The ability of  $1,25(\text{OH})_2\text{D}_3$  to control Th17 responses may be important in severe steroid-resistant asthma, in which dysregulated Th17 responses predominate [19,26,47]. The effect of vitamin D on Th17 often occurs in parallel to an induction of Treg cells, with  $1,25(\text{OH})_2\text{D}_3$  treatment leading to an upregulation of Treg markers such as the transcription factor, Foxp3, and regulatory cytokines such as IL-10 [14,44,48].

In translational studies, Sotirchos et al. [49] compared individuals with multiple sclerosis receiving daily high-dose (10,400 IU) and low-dose (800 IU) cholecalciferol for 6 months with significantly higher serum  $25(\text{OH})\text{D}_3$  ( $P < .0001$ ) at the end of study for the high-dose group. A decrease in IL-17A + CD4+ T cells and effector memory CD4 + T cells was observed in the high-dose group, with a concomitant rise in central memory and naïve CD4 + T cells when compared with low dose. However, no change in serum cytokine levels was reported.

Drozdenko et al. [46] supplemented individuals with increasing daily doses of cholecalciferol and assessed their lymphocyte phenotype *ex vivo*, compared with control individuals. Supplementation yielded an increase in circulatory CD38 + B lymphocytes and a decrease in IFN $\gamma$  + and IL-17A + CD4 T lymphocyte frequency upon *in vitro* stimulation, with no change in IL-4 and IL-10 producers—possibly altering the balance toward a more Th2 and regulatory phenotype. A similar

modulation of the immune response is also reported by Chambers et al. [26], in a randomized controlled trial in which steroid refractory asthmatics were given oral calcitriol ( $1,25(\text{OH})_2\text{D}_3$ ), or placebo for 4 weeks. Supplementation improved dexamethasone (glucocorticoid) responsiveness *in vitro*, including a decrease in IL-17A and increase in IL-10 production with no change in the inhibition of the IL-13 response. Further to this, IL-10 gene induction within  $\text{CD4}^+$  T cells has been observed *ex vivo*, following calcitriol supplementation, in a study where Urry et al. [50] examined adaptive immune cytokine production from steroid-resistant asthmatic individuals supplemented with calcitriol for several days. Supplementation did not affect lymphocyte gene expression of IL-5, IL-13, or IFN $\gamma$ .

In a study comparing inhibition of T cells responses from the peripheral blood and synovial fluid of patients with active rheumatoid arthritis, Jeffery et al. [51] demonstrated greater inhibition of Th17 cells, with or without IFN $\gamma$  co-expression, by  $1,25(\text{OH})_2\text{D}_3$  from the periphery compared with synovial-derived T cells. The authors suggest that phenotype-committed, inflammatory memory T cells such as those found at inflammatory disease sites may be less susceptible to immunomodulation by vitamin D.

In contrast to the immunomodulatory effects of vitamin D supplementation in children and adults on many effector responses, enhancement has been reported in neonates following vitamin D supplementation (4400 IU/day) during pregnancy [52], although the mechanisms underpinning these differing effects are as yet unknown. *Ex vivo* stimulation of cord blood mononuclear cells (CBMCs) with various innate antigens or the mitogen PHA stimulated a higher production of innate cytokines (GM-CSF, IL-6, IL-8). In T cell stimulation cultures, a fourfold greater IL-17A production and greater dexamethasone-induced IL-10 production was reported [52]. Strong innate immune responses in neonates are associated with a reduced risk of infection and probability of asthma development; these data therefore may indicate that restoring vitamin D sufficiency in pregnancy may improve respiratory health in offspring.

## 6.5 T cell plasticity

The aforementioned studies highlight that plasticity occurs within T cell subsets, which can be regulated by vitamin D. For example, the division of T cells into Th17 and Th1 is not as linear as previously assumed, with data showing that Th17 cells can produce both IL-17A and IFN $\gamma$  in response to IL-12 or TNF $\alpha$  stimulation. These cells express both RORC and T-bet, as well as CCR6 and CXCR3, and have been termed Th17.1 cells

(or nonclassic Th1 cells) [53]. It is hypothesized that these cells contribute to the pathogenesis of autoimmune disease, as they are enriched at inflammatory sites in many diseases [54,55]. These cells can respond to  $1,25(\text{OH})_2\text{D}_3$ ; in CCR6 $^+$  cells,  $1,25(\text{OH})_2\text{D}_3$  reduces the expression of IFN $\gamma$ , IL-17A, and double-positive cells [56]. Similar effects have been observed with Th17.1 cells stimulated in response to air pollution particulate matter [57] and in translational studies in SLE patients supplemented with cholecalciferol [49] putting these observations into a relevant therapeutic context. Another important example of T cell plasticity is the capacity of Th effector cells, such as IFN $\gamma$ -expressing Th1 cells to gain and coexpress antiinflammatory cytokines, typically IL-10, which is influenced by vitamin D [13].

## 6.6 T follicular helper (Tfh) cells

Tfh cells are a  $\text{CD4}^+$  T helper cell population that provide help to B cells to promote the production of high-affinity class-switched antibodies, which are central to effective host protection and underpin vaccine efficacy. Tfh cells regulate B cell function by cell surface molecule interactions (e.g., ICOS, CXCR5, and PD1) as well as by soluble factors. The latter include the signature cytokine IL-21, as well as cytokines linked to other Th subsets including IL-4, historically linked to Th2 cells and known to promote B cell antibody production [58]. The VDR is expressed by Tfh, and was increased, in particular in Th1, Treg, and Tfh cells, in SLE patients in comparison with control subjects [59]. Although we are unaware of reports of how vitamin D acts on Tfh, since  $1,25(\text{OH})_2\text{D}_3$  is known to increase several molecules expressed by Tfh (e.g., Th2 cytokines, ICOS1, PD1), but can inhibit the signature Tfh cell cytokine IL-21 in culture [14], it seems probable that Tfh cell function will also be regulated by vitamin D. A recent study analyzed vitamin D status and immune response in patients hospitalized with moderate and severe COVID-19.  $\text{CD3}^+$   $\text{CD4}^+$  T cells, specifically Th2, Th17, and Tfh, were all reduced in the circulation of patients compared with healthy controls, and vitamin D deficiency was associated with the stimulation of Th2 and the downregulation of Th17 cell but no clear impact on Tfh cells. However, this was only assessed in the periphery, and this reflects the challenges of studying human cell populations that are prominent in tissues [60].

## 7. $\gamma\delta$ T cells

The aforementioned studies report effects of  $\text{CD4}^+$  T cells expressing the  $\alpha\beta$  form of the T cell receptor (TCR). An unconventional T cell subset is defined by

expression of heterodimeric TCRs composed of  $\gamma$  and  $\delta$  chains ( $\gamma\delta$  T cells). They represent a relatively minor T cell subset in peripheral blood, but are enriched in peripheral tissues, such as the skin, intestines, and lungs, and are able to rapidly synthesize large amounts of cytokine and are proposed to play a role in tissue homeostasis and immune surveillance [61]. To our knowledge, little work has been undertaken on the effect of vitamin D in  $\gamma\delta$  T cells. Chen et al. showed that  $\gamma\delta$  T cells express VDR upon activation and that production of IFN $\gamma$  and proliferation were inhibited in response to 1,25(OH) $_2$ D $_3$  [62], and it seems probable that vitamin D will regulate many of these functions both directly and through effects on other cells in their local tissue milieu.

## 8. CD8+ T cells

CD8+ T cells play a role in immune defense against intracellular pathogens (e.g., viruses and bacteria), and for tumor surveillance. They possess cytotoxic activity, which can lead to killing of pathogen-infected and tumor cells. They also secrete significant amounts of cytokines and form comparable subsets, based on cytokine profiles, to CD4+ Th subsets. However, considerably less has been reported about the effects of vitamin D on the CD8+ T cell population than on CD4+ T cells. The impact of vitamin D on cytotoxic or CD8+ T lymphocyte immunity to pathogens and cancer was the focus of a review by Sarkar et al. [63] and is discussed in further detail in [Chapter 95](#).

CD8+ cytotoxic T lymphocytes express VDR and CYP27B1 [12,16] and thus are a target for vitamin D. CD8+ T cells are reported to express relatively high levels of VDR following activation [16,63]. Data from mouse models have suggested that cytotoxic T cells are an important source of CYP27B1, raising the possibility that CD8 T cells may play a role in production of 1,25(OH) $_2$ D $_3$  for paracrine effects [12]. In mice, vitamin D inhibits CD8+ T cell proliferation in culture [64]. Human studies also suggest that vitamin D impacts CD8 T cell expansion and frequency, and this has been studied in the context of human aging. In a comparatively small study of healthy women ( $n = 34$ , all  $> 60$  years of age), increased vitamin D levels were associated with a decline of naïve, but an accumulation of effector, CD8 T cells during early aging [65]. In a much larger study of elderly healthy controls ( $n = 461$ ) and patients with age-related diseases ( $n = 8621$ ), across a range of age-related disease types, one of the most striking associations of vitamin D deficiency ( $< 20$  ng/mL or 50 nmol/L) was with an increased frequency of CD8+ T cells [66].

With regard to T cell phenotypes, in vitro human data have shown 1,25(OH) $_2$ D $_3$  can reduce the frequency of

IFN $\gamma$ -producing CD8 T cells [67] and inhibit skewing toward a Th2 phenotype of IL-13-expressing CD8+ T cells [68], which is at variance with several studies of CD4+ T cells, discussed before. Translational studies have suggested that topical calcipotriol (an analog of 1,25(OH) $_2$ D $_3$ ) treatment of psoriatic lesions could reduce the frequency of CD8+ IL-17+ T cells, resulting in clinical improvement [69]. Vitamin D has also been shown to induce regulatory effects in CD8 T lymphocytes. Recent data suggest that in vitro 1,25(OH) $_2$ D $_3$  treatment, with TGF $\beta$  as a required cofactor, induces the immunoregulatory factor alpha-1 antitrypsin (AAT) production from CD8+ T cells, suggestive of an induction of a CD8 population with anti-inflammatory properties, by vitamin D [70]. Notably, the vitamin D precursor, 25(OH)D $_3$ , was unable to induce a similar effect, suggesting that human CD8+ cells, at least under the experimental conditions used, were unable to generate sufficient active vitamin D.

## 9. Actions of vitamin D on regulatory T lymphocyte responses

Immune homeostasis requires not only the effective induction of immune responses but also their timely resolution. Regulatory T lymphocytes (Tregs) are a vital part of the adaptive immune system and prevent excessive inflammatory responses to pathogens that cause tissue damage and pathology. They promote tolerance to commensal flora and are also crucial in limiting responses to self-antigens and to harmless environmental antigens. A reduction in Treg frequency and/or function has been implicated in the pathogenesis of a number of inflammatory diseases including asthma (reviewed in Ref. [71]) and autoimmune conditions [72]. As discussed in the following, vitamin D positively influences Treg function and frequency and is likely to underpin, at least in part, the beneficial relationship observed between vitamin D and immune-mediated inflammatory disease outcomes. This has generated interest into whether ensuring vitamin D sufficiency through supplementation can reduce the risk of common immune-mediated conditions such as asthma in early life [34,35], and by improving the control of existing disease [5].

Distinct populations of Treg exist. The best described populations express the transcription factor Foxp3 (Foxp3+ Treg) and/or the anti-inflammatory cytokine IL-10. Foxp3+Treg are normally generated in the thymus; however, they can also be induced in the periphery from non-Treg (CD25 negative) CD4+ T cells in the presence of anti-CD3/CD28 antibodies, IL-2, and TGF $\beta$  or retinoic acid. Studies in mice and humans [43,73,74] indicate that vitamin D, specifically 1,25(OH) $_2$ D $_3$  increases the frequency of Foxp3+

expressing T cells with inhibitory function. This may be through effects on dendritic cells [75–77], as well as direct actions on T cells [43,74]. Kang et al. [78] reported that  $1,25(\text{OH})_2\text{D}_3$  promotes FOXP3 expression via binding to vitamin D response elements in its conserved non-coding sequence region.

IL-10 expressing Treg cells with suppressive function are also induced by vitamin D in culture, potentially directly and indirectly, via actions on dendritic cells [79]. In more recent reports,  $1,25(\text{OH})_2\text{D}_3$ , alone or together with TGF $\beta$ , induced expression of the serine protease inhibitor,  $\alpha$ -1 antitrypsin by human CD4 [80] and CD8 T cells [70].  $\alpha$ -1 antitrypsin has a range of immunomodulatory properties and IL-10 induction by  $1,25(\text{OH})_2\text{D}_3$  in CD4+ T cells appears partially dependent on the  $1,25(\text{OH})_2\text{D}_3$ -mediated increase in  $\alpha$ -1-antitrypsin [80]. In addition, effector T cells exhibit plasticity and can be induced to co-express anti-inflammatory IL-10 alongside effector cytokines (e.g., IL-17A, IFN $\gamma$ ), which are likely to contribute to the resolution of immune responses [13]. In this system, vitamin D acted on CD4+ T cells activated via the complement system, to drive the transition from single IFN $\gamma$  positive T cells to cells co-expressing IFN $\gamma$  with IL-10 and then single IL-10+ cells. In an elegant and in depth study, the authors demonstrated that vitamin D caused genome-wide epigenetic remodeling and induced and recruited transcription factors (e.g., STAT3, c-JUN, BACH2). These were shown to repress Th1 and Th17 programs and induced IL-10 via IL-6-STAT3 signaling [13].

Many of these original reports of the effect of vitamin D on human Treg arise from laboratory studies and are supported by robust data in animal models. Importantly, translational evidence exists supporting many of these effects in vivo in humans. For example, in asthma, circulating vitamin D levels have been shown to positively correlate with the IL-10 levels and frequency of Foxp3+T cells in pediatric bronchoalveolar lavage [74,81], as well as Foxp3+Treg number in the periphery in adult patients with moderate to severe asthma [82].

Tregs inhibit the function of other lymphocytes, APCs, and innate and structural cells to dampen immune responses through a variety of inhibitory mechanisms. These range from the synthesis of inhibitory cytokines such as IL-10 and TGF $\beta$ , through to metabolic disruption and competition for essential growth factors such as IL-2, by granzyme/perforin-mediated cell cytotoxicity, to effects on the maturation and function of APCs (reviewed in Refs. [72,83]).  $1,25(\text{OH})_2\text{D}_3$  upregulates many of these functions, including inhibitory molecules that Treg are known to express such as CTLA4, PD-1, CD73, and CD200, an area that has been extensively reviewed [3,73].

Our understanding of the breadth of Treg function is expanding, and this brings new perspectives of how vitamin D may influence Treg function and human health. Specialized Treg are reported to be widely present in tissues including visceral adipose tissue, colon, skin, lung, skeletal muscle, and placenta [84–86] where they promote wound healing and tissue repair. For example, in the skin, which is an important site of vitamin D production and metabolism and where Tregs are abundant, Treg may facilitate not only wound healing and repair but also hair morphogenesis and tolerance to skin commensals. Obesity is associated with low serum levels of  $25(\text{OH})\text{D}_3$ , and in adipose tissue, resident Tregs are proposed to regulate adipose tissue homeostasis and limit obesity-associated systemic inflammation [87]. The impact of vitamin D in these tissues, and specifically how  $1,25(\text{OH})_2\text{D}_3$ -mediated effects on adaptive immunity and Treg regulate tissue homeostasis more widely, is an important and evolving area of interest.

Translational studies continue to demonstrate associations between Treg parameters and  $25(\text{OH})\text{D}_3$  status in humans, beyond those described in asthma above, and suggest that maintaining vitamin D sufficiency has the potential to incrementally improve disease outcomes in a range of immune-mediated inflammatory conditions. New approaches are emerging such as a recent study of the use of an injectable hydrogel platform for sustained delivery of anti-inflammatory nanocarriers, and the induction of Treg in atherosclerosis in mice. In this system, the impact of a single slow release bolus of  $1,25(\text{OH})_2\text{D}_3$  may provide advantages to more frequent delivery of soluble  $1,25(\text{OH})_2\text{D}_3$  or  $25(\text{OH})\text{D}_3$  [88]. The immunoregulatory and anti-inflammatory properties of vitamin D continue to be explored as an adjuvant in antigen-specific desensitization therapies [89].

In conclusion, translational studies indicate that vitamin D acts upon T lymphocytes and diminishes IL-17 and IFN $\gamma$ , while enhancing IL-10 responses and Foxp3 Treg frequency not only in the periphery but also in tissues such as the airways. Long-term vitamin D supplementation in multiple sclerosis patients has also been reported to enhance serum TGF $\beta$ -1, although it is unclear whether this derives from lymphocytes or other sources [90]. There is, however, an absence of robust evidence that vitamin D therapies enhance Th2 responses in humans in vivo, although a decrease in Th1/17 frequency without alterations in Th2 inflammation might shift the immune equilibrium in the direction of the latter. In addition, many immunoregulatory functions are reported to be upregulated by  $1,25(\text{OH})_2\text{D}_3$ . These have been described in experimental cultures and frequently supported by in vivo correlates between vitamin D status and specific immune parameters and

following vitamin D treatment of patients. These data argue, plausibly, that despite *in vitro* induction of Th2 responses by vitamin D, the failure to support these data *in vivo* within humans and link them to worsening of Th2-mediated conditions [31] may be because this is balanced against the enhancement of relevant immunoregulatory functions.

## 10. Actions of vitamin D on B lymphocytes

B lymphocytes are key players of the adaptive immune system; they elicit T lymphocyte help and produce pro- and anti-inflammatory cytokines. B cells are characterized by their synthesis of antibodies or immunoglobulins (IgM, IgD, IgG1-4, IgA, and IgE), which are integral to the humoral immune response. Immunoglobulins are central for defense against extracellular pathogens and the efficacy of essentially all vaccine-induced protection to pathogens. However, B cells and antibodies also play a prominent role in allergic and autoimmune disease.

Similar to T lymphocytes, B cells upregulate expression of both VDR and CYP27B1 following activation and are able to synthesize  $1,25(\text{OH})_2\text{D}_3$  [91,92]. However, there are discrepancies between the effect of  $1,25(\text{OH})_2\text{D}_3$  on B cell function *in vitro* and in patient association studies. For example,  $1,25(\text{OH})_2\text{D}_3$  inhibits proliferation and induces apoptosis *in vitro*, while also reducing total IgM and IgG and plasma cell frequency [91,93–96]. These observations have not been recapitulated *in vivo*, in patients with autoimmune disease, as reviewed by Rolf et al. [95].

Of interest in the context of allergic and asthmatic disease, vitamin D treatment of peripheral human B cells in culture reduces IgE production, inhibits antigen presentation functions, and switches toward a regulatory phenotype through increased IL-10 production [92,97,98]. Active vitamin D is observed to inhibit IgE production *in vitro* [96], as well as inhibiting proliferation and differentiation into IgE-, IgG-, and IgA-producing plasma cells and reducing memory B cell formation [97]. The inhibition of IgE class-switch recombination in human B cells is through VDR recruitment of a transrepressive complex to the  $\epsilon$ -germline gene promoter [96].

Many studies on the effect of vitamin D on IgE have been undertaken in mice, with VDR or CYP27B1 knockout mice exhibiting elevated IgE, leading to the conclusion that endogenous calcitriol plays a role in the regulation of IgE, with the potential to limit the development of detrimental allergic responses [99,100]. Observational studies have assessed correlates between IgE and vitamin D status. Hypponen et al. in a large study cohort (> 7000) reported a nonlinear relationship,

with both extremely high, albeit with very low numbers of individuals, and low levels of  $25(\text{OH})\text{D}_3$  associated with elevated IgE concentrations [101]. Gupta et al. [102] reported, in a pediatric cohort, a significant inverse relationship between vitamin D status ( $25(\text{OH})\text{D}_3$ ) with total serum IgE, IgE with specificity for a panel of 5 different aeroallergens, as well as the sum of specific IgE to aeroallergen, but not to sum of specific IgE to food allergens. In a larger cohort, in the National Health and Nutrition Examination Survey 2005–06, vitamin D deficiency was associated with higher levels of IgE sensitization in children and adolescents, including to the food allergen peanut. Notably, no consistent associations were seen between  $25(\text{OH})\text{D}_3$  levels and allergic sensitization in adults [103]. However, vitamin D supplementation (4000 IU/day), compared with placebo for 4 weeks, had no significant effect on serum levels of total IgE, IgE to dust mite, or IgE to cockroach in children with asthma and low vitamin D levels with mean duration of follow-up of 316 days [104].

IgA is required for mucosal immunity, and calcitriol has been observed to control its production in purified human B cells. Notably, calcitriol together with 9-*cis* retinoic acid induced the differentiation of naïve B cells into plasmablasts secreting IgA. This is suggested to require recruitment of the VDR to the TGF- $\beta$  promoter [105]. These two nuclear hormone receptor ligands were proposed to act in an additive, rather than a competitive signaling manner. The authors propose these data suggest that the VDR is a major driver of B cell activation and differentiation, with a potential to channel toward a more protective response.

## 11. Actions of vitamin D on the immune microenvironment and the function of APCs

The capacity of vitamin D to modulate the function of APCs and other cell types, including dendritic cells and macrophages, and structural cells within the local tissue environment, will in turn influence lymphocyte responses. Dendritic cells likely represent an important source of  $1,25(\text{OH})_2\text{D}_3$ , through their expression of CYP27B1 [106,107]. The consequences of vitamin D actions on dendritic cells can result in the failure to activate T cells as robustly, leading to reduced effector responses, and/or to induce tolerance and regulatory T cells.

$1,25(\text{OH})_2\text{D}_3$  has well-documented effects on dendritic cells that influence subsequent immune responses. It acts to maintain an immature dendritic cell phenotype and expression of the monocyte marker CD14, together with reduced expression of CD80/86 and HLA-DR—proposed to be through the inhibition of NF- $\kappa$ B p65 phosphorylation in myeloid, but not plasmacytoid dendritic cells [108,109]. Vitamin D inhibits cytokines

synthesized by dendritic cells that are known to influence T cell phenotype, including two members of the IL-12 family, specifically, IL-12 that drives Th1 responses, and IL-23, which is involved in the maintenance and expansion of Th17 cells [57,110]. This is of relevance in human diseases since Th17 cells in the presence of these cytokines often play a pathogenic role [111].  $1,25(\text{OH})_2\text{D}_3$  also upregulates expression of inhibitory costimulatory molecules, PD-L1 [79] and ILT3 [76], as well as reduced secretion of CCL12 and CCL22, resulting in reduced chemotaxis [109]. Recent data suggest that the mechanism of vitamin D actions involves reprogramming of dendritic cell glucose metabolism [112], fatty acid synthesis [113], and activation of the IL-6-JAK-STAT3 pathway [114]. Of note, pretreatment with vitamin D appears to be required for optimal suppression of proinflammatory responses to TLR stimulation [115]. These data suggest that improving long-term vitamin D status will be required to modulate immune phenotype, and extended periods of supplementation may be required.

Such tolerogenic (immature) phenotypes of dendritic cells induce IL-10-secreting Treg differentiation, elevated IL-10 production, reduced inflammatory cytokines, and reduced proliferation [109,116]. Tolerogenic dendritic cells, induced by a short treatment with VDR agonists, promote  $\text{CD4}^+\text{CD25}^+\text{Foxp3}^+$  Treg cells that are able to mediate transplantation tolerance and to arrest the development of autoimmune diseases [75]. More recently, dendritic cells engineered to produce high concentrations of  $1,25(\text{OH})_2\text{D}_3$  and vitamin A (retinoic acid) augmented the induction of  $\text{Foxp3}^+$  T cells that express the gut-homing receptor CCR9 in vitro as well as in vivo, where they homed to the intestines and could suppress experimental colitis [77]. Some of the proposed mechanisms by which vitamin D may promote tolerance through dendritic cell modulation include expression of PD-L1, IL-10 production, increased expression of membrane bound TNF, and the control of proliferation of inflammatory cell types [79,112,117]. Despite these advances, the mechanism by which vitamin D—treated tolerogenic dendritic cells are able to induce Treg cells remains incompletely understood.

In addition to the effects on antigen presentation, vitamin D can control the levels of soluble mediators produced by other cells in the immune microenvironment including IL-10, IL-12, and IL-23 (discussed before), thereby governing lymphocyte responses, as well as chemokines governing lymphocyte homing [107,118].

Dendritic cells, bronchial epithelial cells, and keratinocytes can also produce  $1,25(\text{OH})_2\text{D}_3$  through their expression of CYP27B1, while  $1,25(\text{OH})_2\text{D}_3$  produced by monocyte-derived dendritic cells has been shown to enhance CTLA-4 expression and reduce IL-17,  $\text{IFN}\gamma$ , and IL-21 expression in cocultured T lymphocytes [14].

Furthermore, both IL-6 and  $\text{TGF}\beta$  can be regulated by vitamin D, both of which modulate regulatory T cell responses [119–121]. Finally, vitamin D can regulate the IL-33 pathway. IL-33 is a proinflammatory mediator released by damaged epithelial cells, which can promote Th2 responses. The soluble receptor (sST2) can antagonize the actions of IL-33. Both  $25(\text{OH})\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$  have been observed to stimulate sST2 production by human bronchial and nasal epithelial cells, while  $\text{CD4}^+$  T lymphocytes produce sST2 in response to  $1,25(\text{OH})_2\text{D}_3$ , but not  $25(\text{OH})\text{D}_3$  (reflective of their low CYP27B1 expression)—thereby inhibiting the actions of IL-33 in culture [15]. This might be predicted to be beneficial in allergic disease but could be counter-indicated in other conditions.

## 12. Effects of vitamin D upon immunometabolism in APC and T cells

One proposed mechanism by which vitamin D alters dendritic cell and T cell phenotype and function is through the modulation of immunometabolism. In recent reports, the immunomodulatory effects of vitamin D have been attributed to its capacity to regulate both fatty acid and glucose metabolism by altering glycolysis, tricarboxylic acid (TCA), and oxidative phosphorylation (OxPhos) rates [108,112,113,122]. Antigen stimulation within immune cells is established to trigger high rates of aerobic glycolysis to support clonal expansion and effector cytokine production [123]. This state of high aerobic glycolysis, known as the Warburg effect, is an adaptation frequently observed in cancer—a disease model in which vitamin D has been found to reduce aerobic glycolysis [124]. On the other hand, vitamin D given during dendritic cell differentiation into tolerogenic dendritic cells has also been found to be dependent upon increases in glycolysis and fatty acid synthesis, albeit with concomitant rises in OxPhos [108,112,113,122].

A decrease in glycolysis has been reported in  $\text{CD4}^+$  effector T cells upon vitamin D treatment, with associated changes in effector function ( $\text{IFN}\gamma$  production), with a lesser response upon oxidative phosphorylation than that reported in dendritic cells [125]. The metabolic effects of vitamin D upon T cells were highlighted through associations with low serum vitamin D and high metabolic rates in PBMCs, followed by findings that  $1,25(\text{OH})_2\text{D}_3$  treatment regulates metabolic regulators, such as c-Myc and mTOR pathway constituents [126–128]. This potential of calcitriol to modulate T cell metabolism may aid in the polarization toward Treg, over a more inflammatory Th17 phenotype [129]. From these data, vitamin D has evident effects upon immunometabolism and signaling pathways such as PI3 kinase/

AKT/mTOR. However, this is a complex field, and reports indicate that responses may differ between cell type, differentiation status, and other variables. Further studies are awaited with interest.

### 13. Translational aspects of vitamin D regulation of adaptive immunity—vitamin D and vaccine responses

Since their introduction, vaccinations have saved and improved the quality of countless lives; however, subgroups of the population exist for whom immune responses to vaccination remain poor, including the very young, elderly, and immunocompromised individuals. This has been further highlighted following the global rollout of COVID-19 vaccinations, to which immunosuppressed individuals exhibit low seroconversion [130], while a recent report suggests that vitamin D sufficiency is beneficial for seroconversion to the SARS-CoV-2 BNT162b2 vaccine [131]. Vaccine efficacy is predominantly reliant on robust, high-affinity antibody responses, which neutralize viruses or toxins, and opsonize pathogenic bacteria. Serum IgG and in some cases additionally IgA (e.g., rotavirus vaccine responses) at mucosal sites are crucial for vaccine success. Most vaccine-induced antibody responses require the help of CD4<sup>+</sup> T cells, particularly Tfh cells—the exception to this being the pure polysaccharide vaccines, which are so-called T cell independent.

The mechanism by which vitamin D may regulate responses to vaccination is plausibly through modulation of both the innate and adaptive immune response. Rapid antigen detection at the vaccination site by dendritic cells and other APCs, migration to draining lymph nodes, and presentation to antigen-specific lymphocytes are required for efficient immunization, a mechanism that paracrine production of calcitriol following TLR ligation was shown to improve in adult mice [132]. One might predict the tolerogenic effect of vitamin D upon APCs and T cells, discussed before, to have a negative impact upon response to vaccination. However, for optimal vaccine responses, class switching from IgM- to IgG-producing B cells is required, and IL-10 secretion has been shown to induce this [133]. Tfh cells are also required for optimal B cell responses to vaccines at the germinal center; however, extensive literature regarding the effects of vitamin D upon these cells is still lacking. There remains limited research into the outcomes of vitamin D treatment upon B cell responses to vaccination [92,97].

Seasonality and latitude are often used as a surrogate for vitamin D status. For example, response to summer inoculation with rubella vaccine in children is modulated when compared with winter, suggesting that higher vitamin D may reduce immunogenicity [134]. However, the immunological effects of ultraviolet B (UVB) generated vitamin D versus supplementation

are not entirely comparable (reviewed in Refs. [135,136]). In contrast, vitamin D deficiency is associated with poor response to measles, hepatitis B, and BCG vaccinations, implying that vitamin D status and UV exposure may not directly align, or that the immunological effects of vitamin D may vary depending upon antigen stimulus [135,137–140]. In the context of influenza vaccines, a systematic review and metaanalysis of studies by Lee et al. [141], to investigate a role for vitamin D<sub>3</sub> deficiency in seroconversion and seroprotection rates, found no significant associations between vitamin D<sub>3</sub> status and vaccine response. They did, however, find that deficient individuals had lower seroprotection rates than sufficient individuals for some strains.

Supplementation studies are fundamental to understanding how vitamin D status may alter or improve vaccination effectiveness, some of which have been reviewed elsewhere [142]. More recently, Goncalves-Mendes et al. [143] investigated the effects of supplementation (100,000 IU/15 days, for 3 months) in elderly (> 65 years of age) vitamin D-deficient individuals upon response to influenza vaccination using a randomized placebo-controlled double-blind trial. Restoring sufficiency did not increase antibody titer, although it did increase Th2/Th1 balance in favor of the former.

### 14. Disparity between association, translational, and clinical studies

Epidemiological studies linking vitamin D status with various health outcomes are frequently indicative of a beneficial effect. Experimental medicine studies of the correlation of vitamin D status or the impact of vitamin D supplementation largely support experimental findings on the impact of vitamin D on adaptive immune parameters, as discussed before, and in many cases plausibly explain epidemiological observations. For example, in chronic airway conditions such as asthma, vitamin D sufficiency is linked to reduced risk for the development of asthma in early life [31,33,36], reduced frequency of exacerbations, frequently caused by respiratory viral infections, and improved responsiveness to treatments such as steroids [5]. Immunologically, 1,25(OH)<sub>2</sub>D<sub>3</sub> is known to enhance a range of antimicrobial pathways (see Chapters 94 and 95). Likewise, as detailed earlier in this chapter, 1,25(OH)<sub>2</sub>D<sub>3</sub> can dampen inflammation, promote pathways associated with peripheral tolerance, and improve the clinical and immune (e.g., reduce Th17 response linked to severe, treatment refractory asthma and boost IL-10 and Foxp3 Treg) response to steroids [5,26,50]. Despite this, clinical findings from vitamin D supplementation trials are frequently inconclusive. Examples of this are given in Table 96.1, in which the details and outcomes of various clinical trials pertaining to the effects of vitamin D supplementation in asthma are shown.

**TABLE 96.1** Study outcomes of vitamin D supplementation in asthma.

Participants	Intervention	Outcomes	References
48 newly diagnosed asthmatic children	500 IU/day cholecalciferol or placebo for 6 months	Significant decrease in exacerbations in vitamin D group	[144]
20 children with chronic asthma	1000 IU/day cholecalciferol or placebo for 1 year	No significant difference in lung function (FEV1) or asthma control test score	[145]
100 moderate–severe asthmatic children	60,000 IU cholecalciferol per month or placebo for 6 months	Significantly reduced exacerbations and corticosteroid requirement in vitamin D group	[146]
130 asthmatics	100,000 IU bolus cholecalciferol intramuscularly plus 50,000 IU/week for 24 weeks or placebo	Significantly improved lung function in the vitamin D group compared with placebo	[147]
23 severe steroid-refractory adult asthmatics	0.25 µg/mL calcitriol twice daily or placebo for 4 weeks	Significantly improved lung function response to prednisolone in vitamin D group	
408 adult asthmatics (VIDA)	100,000 IU single-dose cholecalciferol followed by 4000 IU/day or placebo for 28 weeks	No significant difference in time to first asthma treatment failure; significantly lower inhaled corticosteroid requirement at study end in vitamin D group; borderline significant reduction in cumulative exacerbations with vitamin D supplementation	[148]
250 adult asthmatics (VIDA)	120,000 IU cholecalciferol or placebo every 2 months for 12 months	No significant difference in time to first asthma exacerbation	[149]
44 nonatopic sputum neutrophilic and/or eosinophilic asthmatics	Single-dose 400,000 IU cholecalciferol or placebo. Assessed 9 weeks later	No significant overall difference in sputum neutrophil or eosinophil counts Significantly reduced sputum eosinophils in supplementation group with highest baseline eosinophil levels	[150]
89 asthmatic children	800 IU/day cholecalciferol or placebo for 2 months	Significantly improved asthma control in vitamin D–treated group	[151]

**TABLE 96.1** Study outcomes of vitamin D supplementation in asthma.—cont'd

Participants	Intervention	Outcomes	References
<b>231 moderate–severe asthmatic children</b>	300,000 IU (<5 years) or 600,000 IU (>5 years) intramuscular calciferol, then 400 IU/day cholecalciferol, versus with 400 IU/day only group	No significant decrease in exacerbations over 12 months	[152]
<b>192 moderate–severe asthmatic children</b>	4000 IU/day versus placebo, alongside inhaled fluticasone for 12 months	No significant decrease in exacerbations over 12 months	[153]
<b>250 persistent asthmatic children</b>	1000 IU/day or placebo for 9 months	No significant change in childhood asthma control test score	[154]
<b>112 adult asthmatics</b>	16,000 IU/week calcifediol versus placebo, for 6 months	Vitamin D supplementation significantly improved asthma control test scores	[155]

Divergences between epidemiological and experimental data with clinical outcomes are likely to be due to a combination of factors. Broadly differing participant groups, dosing regimens, including the form of vitamin D prescribed, supplementation methodologies and study endpoints, as alluded to above, are all likely to contribute to this lack of concordance between epidemiology and translational studies. Other possibilities are that elevated serum 25(OH)D<sub>3</sub> levels could be reflective of increased UV exposure and health benefits could be due to vitamin D–independent and UV-dependent mechanisms. Supplementation doses (and/or compliance) often fluctuate greatly, and this could lead to insufficient, or poorly sustained, systemic vitamin D levels, and therefore, shorter dosing intervals with a higher vitamin D dose may be required [156]. Employing different forms of vitamin D could cause more variation in clinical outcomes, as vitamin D intake and serum levels are not always linear [157]. This includes the use of vitamin D<sub>2</sub> versus vitamin D<sub>3</sub>, as their capacity to alter serum 25(OH)D<sub>3</sub> levels and effects upon the immune system are not identical [9,158]. Durrant et al. [9] reported that blood transcriptome analysis following D<sub>2</sub> or D<sub>3</sub> supplementation differentially altered gene expression, with D<sub>3</sub> downregulating the majority of genes, while upregulating type I and II interferon-related genes—a response not observed with D<sub>2</sub> supplementation. Ethnicity can also have an impact upon serum vitamin D levels. Proposed mechanisms for this are decreased UVB absorption in those with darker skin pigmentation, differences in VDR pathway gene expression/polymorphisms, or differences in

parathyroid hormone (PTH) that stimulates renal CYP24A1 expression [9,159,160]. 25(OH)D<sub>3</sub> can, in fact, inversely correlate with 1,25(OH)<sub>2</sub>D<sub>3</sub>, and polymorphisms within vitamin D pathway genes or disease risk genes that may facilitate beneficial immune effects of vitamin D (i.e., 17q21 locus in asthmatic individuals) may confound clinical outcomes [161,162]. Circulating serum vitamin D levels can also decrease during inflammatory responses, as vitamin D is converted to active calcitriol locally [8]. This could indicate that higher levels of vitamin D are required for individuals with inflammatory conditions, such as those highlighted in epidemiological studies.

Conditions that are a result of immune dysregulation, such as asthma, for which vitamin D has been highlighted as a potentially beneficial therapy are often heterogenous in their presentation. To this end, various biologic therapies have failed to be successfully transferred from proof-of-concept studies to clinical trials, unless in well-defined patient endotypes [163]. This may also apply in vitamin D trials, for example, targeting specifically those individuals with significant deficiency at baseline may demonstrate better outcomes—as has been implied by findings in chronic obstructive pulmonary disease [164,165]. It is therefore conceivable that the absence of beneficial vitamin D effects within clinical trial data could be due to inadequate trial design, namely dosing schedules and patient stratification. It is also essential to recognize that diseases that have a component of immune dysregulation cannot be simply attributed to disruption of the adaptive immune system. Applying the pathophysiology of asthma

as an example, in addition to adaptive immune dysregulation, bronchial smooth muscle undergoes hypertrophy, airway remodeling occurs, while the respiratory epithelial integrity becomes compromised. How vitamin D supplementation affects these facets of disease needs to be considered in trial designs.

Restoration of vitamin D sufficiency may not, or only modestly, improve disease symptoms but could alter the local inflammatory milieu to facilitate improved responses to other therapies, as indicated for asthmatic treatment with inhaled corticosteroid treatment, in antimicrobial treatment of tuberculosis and in allergen immunotherapy [50,166,167]. Finally, the age at which vitamin D status restoration occurs is an area where further clinical data is required as, while vitamin D appears to have immunomodulatory effects upon adaptive immunity, various studies investigating the effects of vitamin D supplementation in pregnancy suggest that sufficiency can bolster the immune response in the neonate and early life [35,168].

### 15. Protection from exacerbation of airway disease by vitamin D

While the protective effects of vitamin D are explored to a greater extent in Chapter 44 “Vitamin D and the lungs,” here we will discuss a role for vitamin D within the adaptive immune component of airway disease exacerbations. Exacerbations of chronic airway respiratory disease are commonly caused by respiratory viral infections, and protective effects of vitamin D are likely to be linked to its capacity to enhance antimicrobial pathways [5]. However, periods of poor air quality are associated with increased lower respiratory infections and increased respiratory exacerbations within individuals with chronic respiratory conditions [169–171]. Several studies have associated increased air pollutant concentrations with vitamin D deficiency [172–174]. These pollutants included fine and coarse particulate matter (PM<sub>2.5</sub> and PM<sub>10</sub>, respectively) and nitrogen oxides (NO<sub>x</sub>). Further to this, Bose et al. [175] associated low vitamin D status with increased respiratory episodes in obese asthmatic children in areas with high PM<sub>2.5</sub> concentrations, while a higher vitamin D status was protective against asthmatic symptoms. These associations are frequently attributed to the attenuation of UVB intensity at ground level by high pollutant concentrations, though other inflammatory factors may contribute.

Individuals with chronic respiratory conditions also have hampered natural antioxidant defenses, leaving them particularly susceptible to PM-induced respiratory epithelial damage and inflammation [176]. Oxidative stress is a well-established pathophysiological mechanism of air pollution, and this, even in the absence of

PM, has been found to alter both dendritic cell and lymphocyte responses [177]. For example, increases in oxidative stress (decreased glutathione levels) upregulate costimulatory molecules and IL-12 within dendritic cells and subsequent CD4 T cell expansion in response to LPS, as well as increased IFN $\gamma$  expression in mice with heightened oxidative stress, indicating that an oxidative environment may favor Th1 inflammation [178,179]. At the respiratory epithelium, PM decreases antioxidant defenses and stimulates innate and adaptive immune cell infiltrate, as observed in various in vitro and in vivo human exposure studies [180–182]. Pfeffer and colleagues [182] found that vitamin D pretreatment was protective against PM-stimulated human bronchial epithelial cell (HBEC) inflammation, while bolstering antioxidant defenses and decreasing GM-CSF release by healthy HBECs.

PM pollution can directly alter the phenotype of APCs in vitro and in vivo, inducing dendritic cell maturation, which indirectly impacts CD4 and CD8 lymphocyte responses to exacerbate airway inflammation [57,182,183]. As discussed before, vitamin D promotes a tolerogenic dendritic cell phenotype. Confirming this in the context of air pollution, Mann et al. [57] reported that reference urban PM activated dendritic cells by increasing costimulatory molecule and MHC II expression, which, in turn, drove an IL-17A + IFN $\gamma$  + response in coculture with autologous memory CD4 T cells. This was offset by pretreatment with 1,25(OH)<sub>2</sub>D<sub>3</sub>, in an IL-23-dependent mechanism. In conjunction with epidemiological studies, these mechanistic findings position vitamin D as a promising, readily available, and low-cost therapeutic to counter, at least partially, the adverse effects of air pollutants upon adaptive immunity.

### 16. UVB and vitamin D at the skin—how does this compare with oral supplementation

Vitamin D is largely produced following UVB irradiation of the skin via photolysis of 7-dehydrocholesterol (7-DHC), and its production can therefore be affected by the time/intensity of exposure, clothing, skin pigmentation, and polymorphisms in various enzymes involved in cholesterol synthesis [160]. It is unclear how immunoregulatory properties of vitamin D generated by UVB irradiation differ from vitamin D supplementation (reviewed in Refs. [135,136]); however, it is unlikely that epidemiological studies alone will resolve this question. For example, one argument is that epidemiological associations between low vitamin D status and immunological conditions could be as a result of reverse causation. Reverse causation suggests that systemic inflammation can cause decreases in circulating

vitamin D levels, but also that individuals with immunological conditions may undergo less sunlight exposure [184]. There is, however, limited data available to support this latter theory, while increasing outdoor sunlight exposure can be inadequate in obtaining vitamin D sufficiency in urban children with asthma [175]. Whether vitamin D obtained through supplementation has comparable beneficial effects to those of UVB irradiation-generated vitamin D remains unclear. UV radiation can generate other mediators that may also cause immunomodulation, rendering it difficult to determine the vitamin D–dependent outcomes, and this has been explored in animal models (reviewed in Ref. [135]). Mechanistic studies investigating the effects of UVB irradiation in vivo are limited, particularly within asthmatic individuals, although Malerba et al. have reported in an asthmatic patient suffering from psoriasis that IL-17A and Th1 cytokine expression decreased following UVB phototherapy [185]. This indicates that irradiation can generate similar immunomodulation to that, which is frequently reported from in vitro and translational studies. UV radiation has also been reported to be beneficial in multiple sclerosis, despite using vitamin D status and latitude as a measure of UV radiation levels, thus not considering how vitamin D levels decline with inflammation [186]. Ostkamp et al. [186] also carried out transcriptome analysis upon immune cells from narrowband irradiated patients, in which vitamin D and type I IFN signatures were increased in monocytes, B and T cells, although it is not known if these two signatures have a causative relationship.

Immune cells at the skin represent a unique population that likely have a higher exposure to higher concentrations of vitamin D than immune cells elsewhere within the body. It is, however, worth noting that vitamin D needs to be converted to 25(OH)D<sub>3</sub> before it can be converted to the active calcitriol—whilst the majority of this occurs within the liver by CYP2R1, other cells at tissue sites, including skin dendritic cells, are capable of this and likely to impact local adaptive immune responses [107]. Langerhans cells (LCs) are tissue-resident dendritic cells, which are a target of UV exposure. Murine models have shown that UV irradiation results in LC migration to draining LNs and subsequent Treg induction [187,188]. UV irradiation in mice has also been found to cause immunomodulation of bone marrow–derived dendritic cells, indicative that UV irradiation can have systemic effects—possibly by elevating vitamin D concentrations [189]. However, it is unclear if these responses are truly related to changes in vitamin D concentration as mice lacking the VDR gene have similar levels of Treg induction following UV irradiation to those with wild-type VDR expression [190]. Establishing whether findings from animal models are translatable into mechanisms of human

disease is helpful, and psoriasis is one condition in which UV/vitamin D research is concentrated. Psoriasis is an autoinflammatory disease of the skin, within which Th1/17 inflammation is strongly implicated and is one of the few conditions in which UV radiation is well established to have beneficial and immunomodulatory effects in humans [191–193]. In addition to this, topical VDR agonists (calcipotriol) are used as effective therapeutics, though more evidence is required to confirm that both topical VDR agonists and irradiation have the same effects as increasing systemic vitamin D levels through supplementation [194]. McCullough et al. [195] compiled results from various studies investigating the effects of either oral or topical vitamin D, or sunshine and UVB phototherapy in psoriasis to reveal comparable beneficial outcomes, including in patients with “normal” baseline serum 25(OH)D<sub>3</sub> levels. Overall, these data confirm a beneficial role for oral, topical, and UV-derived vitamin D, although there are likely vitamin D–independent benefits of UV exposure too.

## 17. Conclusions

In conclusion, it is evident that vitamin D has modulatory properties in adaptive immunity; however, VDR expression and subsequent signaling is also required for efficient initiation of classical T cell receptor signaling within naïve T cells [16] and likely other cell types also [105]. This, in addition to other reported functions such as antimicrobial properties, and bolstering of immunity in the neonate positions vitamin D as a unique facilitator of both immune activation and suppression [196]. We therefore envisage that vitamin D acts as a spatial–temporal regulator of adaptive immune responses, upon infection and tissue injury to help initiate efficient, but not excessive, immune responses—see Fig. 96.2. As tissue injury or infection occurs, innate mediators are released that in turn increase vascular permeability, generating a local pool of 25(OH)D<sub>3</sub>. In addition to this, upon exposure to pathogen-associated molecular patterns, Toll-like receptor (TLR) ligation triggers the upregulation of CYP27B1 to accelerate conversion of 25(OH)D<sub>3</sub> into active 1,25(OH)<sub>2</sub>D<sub>3</sub> [197]. The increased levels of active vitamin D would facilitate enhanced lymphocyte activation, antimicrobial peptide production, and autophagy [198] to aid pathogen clearance [112,196]. Finally, as inflammation progresses, a transition to a proresolving environment would occur, increasing IL-10 expression and inhibiting Th1/Th17 inflammation, while the expression of CYP24A1 would form a negative feedback loop to catabolize local active vitamin D. In the absence of sufficient 25(OH)D<sub>3</sub>, such as in vitamin D–insufficient and vitamin D–deficient individuals, inflammation may be sustained and a

**FIGURE 96.2** Vitamin D as a spatiotemporal regulator of adaptive immune responses at sites of inflammation, such as the lung epithelium. We hypothesize that in the healthy airways of vitamin D-sufficient individuals (1), there are low levels of available  $25(\text{OH})\text{D}_3$  and PAMPs, thereby maintaining a baseline expression of TLRs and 1- $\alpha$ -hydroxylase (CYP27B1) within antigen-presenting cells (APCs). This minimizes the availability of  $1,25(\text{OH})_2\text{D}_3$  and T cell activation. Upon lung injury (2), TLR ligands trigger the release of inflammatory mediators, increasing vascular permeability. Increased TLR activation upregulates MHC and CYP27B1 expression within APCs. The latter generates locally available  $1,25(\text{OH})_2\text{D}_3$  that activates vitamin D receptor (VDR) signaling within T cells to have a plethora of effects. These include efficient TCR signaling within naïve T cells, increased antimicrobial responses, autophagy, and effector cytokine production. As the injury progresses (3), there is a surplus of  $25(\text{OH})\text{D}_3$  and  $1,25(\text{OH})_2\text{D}_3$ , which represses major histocompatibility complex (MHC) expression and dendritic cell maturation, simultaneously decreasing T cell activation as a result. T cells exhibit decreased effector cytokine production and skew toward a more regulatory, pro-resolving response. Once injury begins to resolve (4) and pathogens are cleared, homeostasis is restored, decreasing the available  $25(\text{OH})\text{D}_3$  pool. Remaining  $1,25(\text{OH})_2\text{D}_3$  continues to maintain a regulatory T cell response, while increasing expression of the catabolic enzyme CYP24A1.

pathogenic Th1/Th17 inflammation could prevail, particularly in the presence of environmental insults.

## 18. Summary points

- The capacity of vitamin D to modify effector and regulatory CD4+ and CD8+ T cell function is likely to reflect both direct actions on T cells and indirect effects on APCs.
- $1,25(\text{OH})_2\text{D}$  dampens type 1 and type 17 adaptive T cell responses; data are still emerging on the effects on other T cell subsets, e.g., Tfh, unconventional lymphocyte populations, and T cell plasticity.
- Vitamin D can upregulate type 2 responses; however, there is no evidence that this results in exacerbation of conditions linked to type 2 immunity, such as allergic disease or asthma.
- $1,25(\text{OH})_2\text{D}$  promotes a range of immunoregulatory pathways, including increasing the frequency of Foxp3+Treg and IL-10+ T cells, with good evidence linking experimental findings with in vivo observations.
- T cells can generate  $1,25(\text{OH})_2\text{D}$ ; however, the importance of endogenous production by human T cells versus the requirement for production by other cells within the local milieu remains unclear.
- Vitamin D modulates the function of B cells including immunoglobulin synthesis; however, many effects described in vitro have not been recapitulated in vivo. Vitamin D downregulates IgE synthesis, linked to allergic disease and studies in pediatric cohorts demonstrate an inverse association between vitamin D status and total and allergen-specific IgE. The impact of vitamin D on antibody responses to vaccination remains to be fully elucidated.

- The effects of vitamin D on adaptive immunity are predominantly linked to dampening inflammatory responses, which are likely to underpin observational data that vitamin D deficiency is linked to an increased incidence and poor control of many immune-mediated inflammatory conditions.

# Vitamin D, microbiota, and inflammatory bowel disease

*Margherita T. Cantorna and Juhi Arora*

Pennsylvania State University, University Park, PA, United States

## OBJECTIVES

- Present the environmental factors (especially vitamin D and the microbiota) that contribute to the development of inflammatory bowel disease.
- Present the mechanisms by which vitamin D regulates immunity, the microbiota, and experimental inflammatory bowel disease.
- Describe the evidence supporting a role for vitamin D for patients with inflammatory bowel disease.
- Identify the barriers to the use of vitamin D as an adjunct therapy for patients with inflammatory bowel disease.

## 1. Introduction

The Crohn's and Colitis Foundation of America estimates that 3 million Americans have inflammatory bowel disease (IBD). The highest incidence of IBD continues to be in North America and Europe, with the highest percentage of Crohn's disease patients found in Canada [1,2]. However, in the 21st century, IBD has started to occur in Asia, Africa, and South America [2]. Vitamin D deficiency has been linked to the development of immune-mediated diseases, including multiple sclerosis, type 1 diabetes, and IBD [3]. The importance of the commensal microbiota in immune-mediated disease and IBD has been established [4]. In this chapter, the immunoregulatory role of vitamin D and its effect on

the microbiota and the pathology of IBD will be reviewed. The epidemiological evidence connecting vitamin D deficiency to IBD severity, and the data from animal models of experimental IBD will be discussed. Finally, current treatment options for IBD patients will be reviewed, and how vitamin D might be used as an alternative, or a supplemental treatment for patients with IBD.

## 2. What is inflammatory bowel disease?

IBD occurs because of complicated interactions between multiple genetic and environmental factors. Crohn's disease (CD) and ulcerative colitis (UC) are the major forms of IBD. CD and UC are chronic inflammatory disorders of the gastrointestinal tract that are characterized by remitting and relapsing inflammation of the intestinal mucosa [5]. The IBD diseases often result in abdominal pain, diarrhea, and fever. As the disease progresses, rectal bleeding, weight loss, and severe fatigue can occur limiting the quality of life for patients with IBD. Men and women are equally affected by IBD. CD affects teens and young adults with the majority of patients being diagnosed between the ages of 15 and 35 years, and UC affects slightly older individuals; UC patients are usually diagnosed in their mid to late 30s [6]. Because the symptoms of CD and UC are similar, ~10% of patients cannot be definitively diagnosed, and these cases are termed indeterminate colitis. Even though CD and UC share similarities, there are distinct differences in their pathology. The inflammation found in CD most commonly involves the terminal ileum of the small intestine but can be diffuse affecting areas

from the esophagus all the way to the rectum [5,7]. CD is characterized by aggregates or clusters of immune cells, specifically macrophage and T cells that form granulomas; therefore, CD is sometimes described as a granulomatous or granuloma-forming disease [6,7]. Inflammation in CD can be patchy or segmental. These are referred to as “skip” lesions [6,7]. The lesions can become transmural, affecting the entire thickness of the intestinal wall. Unlike CD, inflammation in UC typically involves the rectum and extends proximally in a continuous lesion. Histopathology of UC shows an increase in white blood cells in the lamina propria of the colon and the crypts, which often leads to the development of microabscesses [6,7].

Normally, the body’s immune system protects from invading pathogens such as bacteria, viruses, and fungi but tolerates food antigens and microbes living in the lumen of the intestine. However, in IBD, the immune system is inappropriately activated by the microbes found in the gut. In patients with IBD, the inflammation does not resolve but instead persists. A complicated interplay between genetics and the environment predisposes individuals to the development of IBD. Current research focuses on understanding how the balance between bacteria, the host, and the immune system is maintained, so that new strategies to prevent or treat IBD can be discovered.

### 3. Who gets inflammatory bowel disease?

#### 3.1 Genetic factors

There is clear evidence of a strong genetic component to IBD. IBD is significantly more prevalent within families. In fact, 20%–25% of patients have a close relative with CD or UC [8]. People with a biological relative with IBD are 10 times more likely to develop the disease than the general population and that number increases to 30 times more likely if the relative is a brother or sister [9]. Advances in genetics research have led to the discovery of several IBD susceptibility genes [10].

Single-nucleotide polymorphisms (SNPs) in genes of the immune system are prevalent in IBD [11]. The major histocompatibility complex (MHC) is expressed on all nucleated cells and controls the generation of antigen-specific immunity. MHC genes regulate the ability of the immune response to distinguish between self-antigens and foreign antigens. In immune-mediated diseases including MS, rheumatoid arthritis, and IBD, the immune response inappropriately targets host tissues. SNPs in MHC genes have been described in patients with these immune-mediated diseases. SNPs in MHC affect the nature of the immune response and are associated with IBD [11].

Additional IBD-associated genes have been identified that regulate immune cell development, function, or activation [10]. Some genetic polymorphisms found in patients with IBD affect the function of the immune system by altering the immunomodulatory cytokines produced by it. Interleukin (IL)-10 is an important suppressive cytokine, and SNPs in and around the IL-10 gene have been associated with UC [12]. SNPs in inflammatory cytokine genes or in genes for receptors of inflammatory cytokines, including tumor necrosis factor (TNF)- $\alpha$ , IL-8, IL-12, IL-18R, and IL-26, have been described in patients with CD and UC [11–14]. Several SNPs in genes associated with IBD play a role in the development of inflammatory T cells. Subsets of these genes encode cytokines or cytokine receptors that affect Th17 differentiation (IL-23 receptor) [11]. SNPs have been described that can affect or disrupt the IL-23R signaling cascade including STAT3 and STAT4 (associated with CD and UC, respectively) and JAK2 (associated with both) [15]. Another IBD susceptibility gene is CTLA4, which can suppress T cell activation [16]. An important IBD susceptibility gene is nucleotide oligomerization domain (NOD)2 (also known as CARD15) [10]. SNPs of NOD2 have been shown to limit the immune system’s ability to recognize bacteria [11]. NOD2 encodes a cytosolic microbial molecular pattern recognition receptor (PRR) that belongs to a large group of innate immune receptors [6]. Like NOD2, NOD1 is also a PRR, but NOD1 SNPs are more strongly associated with UC than CD [17]. Toll-like receptor (TLR) 4 recognizes bacterial lipopolysaccharides and helps activate the immune response to invading microbes. Polymorphisms in the gene encoding TLR4 have been shown to be associated with both CD and UC [18]. In each of these cases, failure to recognize bacteria properly may result in an abnormal immune response to commensal microflora.

Other IBD susceptibility genes have roles in maintaining intestinal integrity. Extracellular matrix protein 1 is implicated in the interaction between the intestinal epithelium and the basal membrane, and SNPs in the gene encoding this protein have a strong association specific for UC [12]. NOD-like receptor protein 3 SNPs are associated with CD, and in mouse models, loss of this protein has been shown to result in the loss of epithelial integrity [19,20]. Loss of intestinal integrity may result in systemic infiltration of commensal flora and increased inflammation in the underlying tissue.

To date, over 500 SNPs have been discovered in genes of the vitamin D pathway with 470 of the SNPs being found within the VDR gene [21]. The VDR gene maps to a region on chromosome 12 that has been functionally linked to IBD by genome-wide association [22]. Through the use of genome-wide association studies, polymorphisms in the VDR gene were shown to increase

susceptibility to CD and UC [22,23]. A meta-analysis of studies done before 2014 showed that there is one polymorphism in the VDR that is associated with higher risk of CD and one VDR polymorphism associated with a lower risk of UC [24]. Additional studies are needed to determine the extent of VDR polymorphisms in patients with IBD and whether the polymorphisms result in functional outcomes in vitamin D signaling.

1,25-Dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ), the hormonal form of vitamin D, is known to be a transcriptional regulator that targets genes via interaction in trans with vitamin D response elements (VDREs). Several IBD-associated genes have VDREs. Cytokine genes such as IL-2, IFN- $\gamma$ , IL-12, and others are transcriptional targets of  $1,25(\text{OH})_2\text{D}$  [25]. Sequence analysis of human MHC class II genes revealed VDREs in the promoter [26,27]. The IBD-associated gene NOD2 is regulated by vitamin D and has an enhancer VDRE [28]. Vitamin D is a transcriptional regulator of several genes important in controlling the immune response and the development of IBD.

Other pathways that control vitamin D function, beyond the VDR polymorphisms, have not been examined in relation to IBD. There is evidence that SNPs within the gene encoding the vitamin D- $1\alpha$ -hydroxylase (*CYP27B1*) or the vitamin D 25-hydroxylase (*CYP2R1*) that is required for production of  $1,25(\text{OH})_2\text{D}$  are associated with MS [29,30]. SNPs in the genes of other components of the vitamin D pathway have been described including genes for vitamin D catabolism and the vitamin D-binding protein [21]. The effects of vitamin D and its metabolites could be regulated by alterations in genes that affect vitamin D transport, metabolism, catabolism, or function. To date, these genes have not been studied in IBD patients.

### 3.2 Environment

Genetic polymorphisms account for only 10%–20% of the overall risk in CD and even less for UC [31]. The concordance rate for IBD development in genetically identical twins is only 20% in UC and 50% in CD [3]. These findings indicate that important environmental factors affect the development of IBD.

IBD is largely a disease of the developed world, with the majority of cases being reported in North America and Europe. IBD occurs more often in urban than in rural areas, and within the northern hemisphere, IBD is more prevalent in northern versus southern climates [2,32]. The prevalence of IBD worldwide and specifically in countries that were previously considered “low-incidence areas,” such as Japan and India, is also increasing [2]. The increased prevalence of IBD cannot be explained by genetics. First- and second-generation

immigrants from “low-incidence areas” that have moved to countries with higher incidences adopt risk levels similar or higher than the residents of that country [11].

The environmental factors that may play a role in IBD are poorly defined and may be numerous. The incidence of IBD is higher in industrialized nations and even more so for urban areas within those nations. Environmental factors that may be different in IBD low versus high areas include the following: diet, lifestyle, pollution, exposure to potentially harmful chemicals, and exposure to smoke. Smoking tobacco is one of the most highly associated risk factors for CD but interestingly has been shown to be helpful in patients with UC [33].

One critical environmental factor associated with IBD is the microbiota. Bacterial exposure can be shown to either induce or prevent experimental IBD. In one animal model of IBD, germ-free mice are protected and in another experimental model germ-free mice develop more severe disease [12,34]. Infection with *Mycobacterium avium paratuberculosis* and several species of *Helicobacter* is associated with IBD [35,36]. The causative and/or protective role of the microbiota has been demonstrated by microbial transplants into germ-free or antibiotic-treated animals that result in changes in the severity of experimental colitis [37,38]. Microbial transplants have also been done in humans with some success, especially in UC patients [39–41]. The composition of the microbiota is of critical importance for health, and dysbiosis is linked to the development of IBD.

### 3.3 Microbiota in health and disease

A population of nearly 100 trillion dynamic and diverse microbiota—between 500 and 1000 different species—inhabit the human gut [42]. The gut microbiota is essential for normal immune system development, displacement of pathogens, and extraction of additional energy (e.g., short-chain fatty acids) from otherwise non-digestible dietary substrates [43–45]. Highlighting the importance of the gut microbiota, numerous human metabolic diseases and conditions have been attributed to significant alterations in the microbiota [44]. For example, IBD is associated with less diversity in microbiota and an expansion of opportunistic pathogens that cause severe intestinal inflammation [44,46]. The composition of the microbiota also regulates health and diseases outside of the gastrointestinal (GI) tract including multiple sclerosis, cancer, and neurological diseases [47,48]. Regulation of the microbiota is important for the maintenance of health and homeostasis.

The human infant is largely germ-free until after birth. As babies are born microbiota, antibodies and nutrients are transferred from the mother to the neonate

[49,50]. Maternal antibodies help to protect the neonate from infection as the baby develops [51]. The microbial colonization of the neonate plays a critical role in the expansion of innate immune cells, development of intestinal epithelial cells, and establishment of a complex and diverse microbiota [50]. Evidence suggests that the changes in the microbiota that occur early in life can persist and may partially explain increased risk for disease later in life [52,53]. Over the lifespan of individuals, the microbiota continues to change with age, diet, and antibiotic use.

Acquired immunity requires the microbiota. Adult germ-free mice have very small lymph nodes and low levels of IgA, IgM, IgG antibodies, and very high IgE levels [54]. The elevated IgE in the germ-free mice was shown to be a result of elevated IL-4 and increased type 2 responses [54,55]. Colonization of the germ-free mice with microbiota reduced IL-4 secretion and down-regulated the IgE response [54,56]. Colonization of mice with intact microbiota was shown to induce type 1 T helper (Th1) T cells, Th17, and regulatory T cells (Treg) in the GI tract [57]. A key microbe for the induction of Th17 cells in the GI tract was shown to be segmented filamentous bacterium [57]. Microbe-specific regulatory T cells (FoxP3/ROR $\gamma$ t+) have been described in the colon of mice that help in maintaining immune tolerance and the balance between pro- and antiinflammatory responses [55,58]. Microbial transplantation into germ-free mice reconstituted the FoxP3/ROR $\gamma$ t T reg cells and demonstrated their dependence on the microbiota [55,58]. *Bacteroides* and *Clostridium* species are among the bacteria that induce T reg cells [59,60]. T and B cell homeostasis depend on the commensal microbiota.

Changes in the diet impact the microbiota. Dietary change resulted in a rapid but reproducible change in the microbiota of mice [37,61]. Experimentally in mice, the diet affected the host microbiota more so than genetics [61]. Beginning with the choice to breastfeed or formula-feed, the effect of diet on the human microbiota has been demonstrated [52,53,62]. The Mediterranean diet and the Western diet are two extremes that have been shown to have opposing effects on the development of chronic disease [62]. The key differences between the Mediterranean versus Western diets are the lower amounts of animal fats/protein, lower sugar, higher and more varied fiber, and higher plant protein. Feeding Western diets to mice resulted in a shift in the microbiota within 3.5 days [61]. The microbiota of the mice fed Western diets had reproducible increases in Firmicutes and Verrucomicrobia and decreased Bacteroidetes phyla [61]. Obesity, which is associated with the consumption of western diets, resulted in higher Firmicutes/Bacteroidetes ratios [63]. The Firmicutes/Bacteroidetes ratio of individuals who adhered to a Mediterranean diet were lower than those who did not

in the PREDIMED (PREvencion con Dieta MEDiterranea) study [64]. In addition, the participants that had eaten a Mediterranean diet had higher Bacteroidetes phyla [64]. Another indication of adherence to the Mediterranean diet was an increase in short-chain fatty acids produced by the microbial metabolism of fiber [64]. The health-promoting effects of the Mediterranean diet and the disease-inducing effects of Western diet have profound effects on the commensal microbiota.

Manipulation of the microbiota is not limited to macronutrient intakes. In mice, changing or adding a single component to the diet alters the microbiota [37,65]. White button mushroom feeding altered the microbiota and improved glucose sensitivity compared with the control fed mice [66]. Single micronutrient deficiencies, including vitamin A and vitamin D deficiency, shift the composition of the microbiota [38,67,68]. There is a dominant effect of diet on the microbiota of an individual. The efficacy of interventions, such as microbial transplantation or probiotics, to shift the microbiota toward health promotion, will be affected by the diet. Approaches that seek to manipulate the microbiota would need to include lifestyle diet changes to sustain the healthy microbiota. Whether single nutrient or other dietary interventions can cause stable and long-term shifts in the microbiota to promote health is an open question.

### 3.4 The “hygiene hypothesis”

The higher incidence of IBD in industrialized countries has led to the proposal of the “hygiene hypothesis.” The hygiene hypothesis suggests that because of the use of vaccines, improved sanitation, and reduced rates of infection, the immune system does not receive critical signals, which impact the development of the immune system and result in increased incidence of immune-mediated disease [69]. The immune system overreacts and subsequently fails to shut down inflammation [32]. Rural areas have fewer cases of IBD. Several studies have shown that children who live on farms have a lower prevalence of immune-mediated diseases including asthma, allergies, and IBD [32,69]. Data indicate that elements of the farm lifestyle may expose children to factors that activate the immune response but do not cause inflammation. Possibilities include exposure to endotoxins, contact with animals or soil, microbial exposure, and diets rich in dairy products [32,69]. Interestingly, in 2007, a case-controlled study showed that exposure to farm animals, especially cattle, during the first year of life had a protective effect against developing IBD [70].

Improved hygiene in developed countries limits exposure to previously ubiquitous infectious agents such as several different types of worm (helminth)

infection. Helminths are parasites that infect humans throughout the world and are thought to play an important immunoregulatory role in the intestine. The response of the immune system to helminths, such as *Schistosoma mansoni* and *Trichinella spiralis*, has been shown to be protective against experimental models of IBD and in patients with IBD [11]. In addition, infection with these organisms results in reduced inflammation and increased production of mucins and water secretion into the lumen of the gut, which also reduces inflammation [32]. Epidemiological data suggest that helminth infection is inversely correlated with the economic status of the region as well as incidence of IBD and other immune-mediated diseases [11].

### 3.5 The “vitamin D hypothesis”

The vitamin D hypothesis has been proposed and suggests that vitamin D status may be an environmental factor involved in the development of IBD [71,72]. A major source of vitamin D comes from a photolysis reaction in the skin after exposure of skin to sunlight. Skin pigment, aging, time of day, season, and latitude dramatically affect vitamin D synthesis [73]. The incidence of IBD is higher in more northern regions of the United States and Canada. Vitamin D status is especially low during winter months in areas with the greatest seasonal fluctuation [73,74]. Many of the environmental factors that are present in high-risk areas for IBD would also result in decreased availability of vitamin D. Factors such as air pollutants and decreased outdoor activity are known to reduce vitamin D synthesis [73]. Intentional avoidance of sunlight exposure of our skin also reduces vitamin D production in the skin. In developed countries, people limit skin exposure to sunlight to avoid skin cancer. The use of high SPF sunscreens not only decreases the risk of skin cancer but also reduces the amount of vitamin D made in the skin [73].

The other source of vitamin D is the diet. Most diets are limited in natural sources of vitamin D. Vitamin D–fortified dairy and grain products, egg yolk, and ultraviolet B-exposed mushrooms contain some vitamin D [75]. Oily fish such as salmon or cod are high natural sources of vitamin D [75]. Obesity results in lower serum levels of 25-hydroxyvitamin D (25(OH)D) [76], and obesity in IBD patients is associated with increased severity of IBD [77].

Vitamin D insufficiency (25(OH)D 20–35 ng/mL) and deficiency (<20 ng/mL) are common in northern regions of the northern hemisphere, and several studies report an even higher prevalence of insufficiency and deficiency in adult and pediatric patients with IBD [78]. Vitamin D deficiency is common even when the patient is in remission [78,79]. Several biomarkers

indicative of inflammation (fecal calprotectin and IL-6) have been shown to be inversely associated with vitamin D status [80,81]. Conversely, the antiinflammatory cytokine IL-10 was higher with increased serum 25(OH)D levels [82]. Vitamin D deficiency was associated with high prevalence of osteoporosis, osteopenia, and low bone mineral density (BMD) in patients with IBD [83]. Similarly, IBD patients have a higher rate of bone fracture [84]. These trends may be a consequence of the disease, and/or glucocorticosteroid treatment that has been shown to decrease BMD. Many newly diagnosed IBD patients have reduced BMD, and the increased IBD prevalence is slightly higher in patients with CD than UC [85]. Low serum 25(OH)D levels are a common finding in patients with IBD and may both predispose and exacerbate IBD that contributes to the development of bone disease.

Several cross-sectional and observational studies have been performed (Table 97.1; [96]) to investigate the association between the severity of UC or CD and serum 25(OH)D levels (Table 97.1). Patients with vitamin D deficiency had more severe UC [86–91]. Vitamin D insufficiency led to relapses that were closer together than in vitamin D–sufficient UC patients (Table 97.1; [87,88]). Vitamin D status was associated with improved quality of life for UC patients [86,90]. Vitamin D deficiency or vitamin D insufficiency was associated with higher CD disease and longer CD duration than vitamin D–sufficient CD patients (Table 97.1; [89,91–95]). Multiple studies establish an inverse correlation between vitamin D status and the severity of both UC and CD.

### 3.6 The gut epithelium, commensals, and inflammatory bowel disease

The gastrointestinal tract and the mucosal immune response form a barrier designed to allow nutrient and water absorption but not systemic infection with the microbes harbored in the gut. Maintaining the mucosal barrier function of the gastrointestinal tract is critical, and patients with IBD have increased permeability of the small intestine and colon that leads to malabsorption and systemic exposure to microbes [97]. Expression of tight junction proteins such as claudin-1, ZO-1, occludin, and E cadherin by epithelial cells in the gastrointestinal tract maintains epithelial integrity [97]. Experimental models of IBD show increased gastrointestinal tract permeability; as a result, the animals have leaky guts [98,99]. Compromised barrier function in both humans and experimental animals is linked to inflammation, colitis, and IBD.

IBD is associated with less diversity in microbiota, dysbiosis, and an expansion of opportunistic pathogens

**TABLE 97.1** Associations between serum 25(OH)D levels and clinical IBD severity.

Parameter <sup>a</sup>	Serum 25(OH)D <sup>b</sup>			Reference(s)
	Deficient (<20 ng/mL)	Insufficient (20–35 ng/mL)	Sufficient (35–80 ng/mL)	
UC severity	+++	+	+	[86–91]
UC duration	+++	+	+	[87]
UC relapse	ND	++	+	[88]
UC quality of life	ND	+	–	[86,90]
CD severity	+++	++	–	[89,91–95]
CD duration	++	+	–	[91]

<sup>a</sup>Parameter and the association with IBD disease: –, remission; +, mild disease; ++, moderate disease; +++, severe disease.

<sup>b</sup>A range of cutoffs were used to define the 25(OH)D level between vitamin D insufficiency and sufficiency: 30, 32, and 35 ng/mL of 25(OH)D. UC, ulcerative colitis; CD, Crohn's disease; ND, not determined.

that cause severe intestinal inflammation [100,101]. Patients with IBD had fewer commensal from the phyla Firmicutes and Bacteroidetes and higher potentially pathogenic Proteobacteria and Actinobacteria phyla members [101]. In particular, bacteria that ferment non-digestible dietary fiber into butyrate are lower in IBD patients as compared with healthy controls [101]. Nonbacterial members (viruses and fungal microbes) of the microbiota have also been described as being in dysbiosis in IBD patients [102,103]. The composition of the gut microbiota is critical for the maintenance of gastrointestinal homeostasis. Dysbiosis of the bacteria, viruses, and fungi is associated with the development of IBD.

#### 4. The immune system and inflammatory bowel disease

The gastrointestinal immune system is a population of heterogeneous cells whose role is to maintain tolerance of the large number of antigens present in food as well as the abundant microbiota. The mechanisms by which tolerance in the gut is controlled includes complex interactions between the microbiota, the innate, and adaptive immune systems.

In healthy intestine, the epithelium provides a tight barrier and interacts with the commensal microbiota at the mucosal interface (Fig. 97.1). Vitamin D receptors are expressed constitutively in epithelial cells found in the small intestine and colon, and the deletion of the VDR in the gut epithelium resulted in an impaired barrier and increased susceptibility to experimental colitis [104]. Vitamin D and 1,25(OH)<sub>2</sub>D induce the expression of several different proteins (ZO-1, claudins, and E-cadherin) important for the integrity of the gut barrier [104–106]. The gut is largely tolerant of the commensal

bacteria and does not mount an immune response to it. Injury of the gut results in impaired intestinal permeability and dysbiosis of the microbiota with a shift in the microbiota that favors pathogens such as the Proteobacteria phyla members (Fig. 97.1; [107]). Following injury, including gastrointestinal infection, the mucosal immune system mounts an immune response to clear the infection and then reinstates homeostasis. The innate immune system is the first line of defense against an invading pathogen. Innate immune cells such as macrophage and dendritic cells (DCs) recognize pathogens via pattern recognition receptors (TLRs or NOD-like receptors) and become activated. Activated cells then become antigen-presenting cells; they process peptide components of the pathogen and present these antigen peptides to T cells in the local environment. The type of T helper (Th, CD4<sup>+</sup> T cell) response that is generated will dictate the outcome of the infection.

Different T cells are required to induce protection from different pathogens. Effector T cell responses including Th1 and Th17 cells are required to fight many different gastrointestinal infections. In IBD uncontrolled Th1 and Th17, immune responses occur (Fig. 97.1) and strategies to suppress the Th1 and Th17 cells effectively suppress experimental IBD. Patients with IBD often have increased Th1 cells in the intestine that produce high levels of the Th1 inflammatory cytokine IFN- $\gamma$  [108]. Th17 cells produce IL-17 that has been shown to play a pathogenic role in several immune-mediated diseases including MS, type 1 diabetes, and IBD [109,110]. Clearance of enteric infections requires the induction of antigen-specific Th17 cells [111]. The IL-17 produced at the peak of infection with enteric pathogens has been used to model the GI inflammation that occurs with enteric infection [111]. Resolution of the GI inflammation following infection requires the inhibition of Th17 cells and the induction

**FIGURE 97.1** Vitamin D maintains homeostasis of the gastrointestinal tract. Vitamin D sufficiency and the healthy gastrointestinal tract: The mucosal epithelium forms a barrier to prevent infection with the microbes found in the gut. The healthy gastrointestinal tract harbors a diverse population of microbes. The microbes in the vitamin D-sufficient gut induce FoxP3<sup>+</sup>/RORγt<sup>+</sup> T reg cells. The vitamin D-sufficient intestinal epithelial cells express ZO-1, occludin, and claudin that are important tight junction proteins required for an intact barrier. Vitamin D supports ILC3 cells that produce IL-22 important for maintaining barrier integrity, responding to microbial antigens and regulating T cell responses. With the participation of dendritic cells, naïve Th cells require vitamin D to generate enteric specific Th17 cells. In the healthy intestine, there is a balance between effector T cells (Th1 or Th17) and regulatory T cells (CD8αα, Treg, and iNKT cells) that prevent the host from generating an immune response to the commensals, while protecting from gastrointestinal infection. The gut epithelium during vitamin D deficiency is impaired, and dysbiosis occurs that breaches the mucosal barrier. The microbiota in the vitamin D-deficient host has increased numbers of proteobacteria, increased firmicutes/bacteroidetes ratios, and a decrease in the diversity of the microbes in the gut. The vitamin D-deficient gut has fewer commensal microbiota that can induce FoxP3<sup>+</sup>/RORγt<sup>+</sup> T reg cells. The dysbiosis and shift toward pathogenic bacteria leads to increased DC activation, antigen presentation, and cytokine production. Infection-induced Th17 cells are slow to develop in the vitamin D-deficient host. Overproduction of IL-17 and IFN-γ occurs in the vitamin D-deficient host. In addition, there are few regulatory cells and less IL-10 in the vitamin D-deficient gut. Too few iNKT cells and CD8αα T cells result in the inability to turn off the Th17 and Th1 cell response, and as a result, inflammation and colitis develop. IFN, interferon; ILC, innate lymphoid cell; IL, interleukin; iNKT, invariant natural killer; Th, T helper cell; Treg, T regulatory cell. Created with BioRender.com.

of Treg cells (Fig. 97.1; [111,112]). Some patients with UC have an increased Th2 cell response that is characterized by the production of IL-4, IL-5, and IL-13 instead of the Th1 and Th17 cell cytokines [113,114]. In addition, CD patients that are anti-TNF-α nonresponders had Th2 cells in the lamina propria [113]. Uncontrolled Th1, Th17, or Th2 cell responses are associated with both UC and CD.

There are a number of other types of T cells that play a role in turning off (regulating) immune responses in the gut (Fig. 97.1). The invariant natural killer T (iNKT) cells produce cytokines early during an immune response

acting on the DC and influencing the development of the T cell responses. iNKT cells in the intestine become activated by the epithelial cells to produce inhibitory cytokines such as IL-10 [115]. iNKT cells are early producers of many cytokines including IFN-γ, IL-4, IL-13, and IL-10 [115]. The type of cytokines produced by the iNKT cells dictates the nature of the resulting T cell response [115]. Activation of iNKT cells protects mice from experimental IBD, and reduced numbers of iNKT cells have been shown in experimental MS and type 1 diabetes [116]. IBD patients have decreased numbers of iNKT cells [117]. FoxP3<sup>+</sup> CD4 T cells (Treg) act to inhibit

the proliferation of T cell responses both in vitro and in vivo [118]. Animals that lack Treg cells spontaneously develop experimental IBD [12]. The spontaneous development of IBD in mice that lack Tregs is because of the inability to turn off T cell responses to the commensal flora [12]. T regs in the GI tract can be FoxP3+ or FoxP3+/ROR $\gamma$ t+ [119]. In the colon lamina propria, most of the Tregs are FoxP3+/ROR $\gamma$ t+ and require microbiota since they are largely absent in germ-free mice [55]. Tregs have been shown to induce programmed cell death or apoptosis in effector T cells (Th1 and Th17 cells), suppress proliferation, and produce the suppressive cytokines IL-10 and TGF- $\beta$ 1 [118]. Transfer of Tregs has been shown to suppress experimental IBD in vivo [59]. iNKT cells and Tregs downregulate and control the Th1 and Th17 responses in the gastrointestinal tract (Fig. 97.1).

The normal vitamin D-sufficient gut-associated lymphoid tissue harbors specialized gut-specific T cells that also have a regulatory function. These unique T cells express a homodimeric form of CD8-CD8 $\alpha\alpha$ ; the CD8 $\alpha\alpha$  on the T cells acts to dampen signals coming into the cell through the T cell receptor [120]. CD8 $\alpha\alpha$  is expressed on T cells in the gut to prevent them from responding to the bacteria and food antigens found there (Fig. 97.1; [121]). In addition, CD8 $\alpha\alpha$  T cells in the intestinal epithelium can also suppress inflammation by producing suppressive cytokines such as IL-10 and TGF- $\beta$ 1 [122,123]. Adoptive transfer of CD8 $\alpha\alpha$  T cells has been shown to suppress experimental IBD [122]. Unique T cells that express CD8 $\alpha\alpha$  are regulatory cells in the gut.

#### 4.1 Vitamin D regulates T cell responsiveness

As discussed elsewhere in this volume, the VDR is expressed in all immune cells that have been examined. The level of VDR expression in certain types of immune cells including T cells increases after activation [124]. Vitamin D deficiency or VDR knockout (KO) mice have been shown to have increased susceptibility to several different experimental models of IBD, including infection-induced colitis [125–127]. In addition, the high-affinity ligand for the VDR, 1,25(OH) $_2$ D, suppresses experimental models of immune-mediated disease including IBD [128,129].

Treatment with 1,25(OH) $_2$ D in vitro has been shown to inhibit differentiation and activation of DC [130]. 1,25(OH) $_2$ D-treated DC stay in a more immature state characterized by reduced antigen presentation, decreased IFN- $\gamma$  production, and increased production of IL-10 [131,132]. Macrophage proliferation and differentiation is also inhibited by 1,25(OH) $_2$ D in vitro, and treatment of the macrophage after activation inhibits

the production of IL-12 and TNF- $\alpha$  [133,134]. These effects on macrophage and DC result in reduced Th1 cell activation.

T cells are also direct targets of 1,25(OH) $_2$ D. Purified T cells activated and 1,25(OH) $_2$ D $_3$  treated had lower proliferation and less IL-2 and IFN- $\gamma$  production [135,136]. Conversely, CD4 $^+$  Th cells from VDR KO mice overproduce IFN- $\gamma$  and proliferate twice as quickly in mixed lymphocyte reactions [125]. Treatment of peripheral blood mononuclear cells from IBD patients with physiological levels of 1,25(OH) $_2$ D decreased the production of IFN- $\gamma$  [137]. IL-4 inhibits Th1 cells, and IFN- $\gamma$  inhibits Th2. Treatment of either human or mouse T cells and iNKT cells in vitro with 1,25(OH) $_2$ D induced IL-4 production [138]. Several groups have shown that 1,25(OH) $_2$ D treatment enhances the production of IL-4 and IL-5 and augments the expression of the Th2-specific transcription factor GATA-3 [139,140]. 1,25(OH) $_2$ D inhibits Th1 and induces IL-4 production from Th2 and iNKT cells.

Th17 cells are also targets of 1,25(OH) $_2$ D. 1,25(OH) $_2$ D treatment of DC reduces Th17-inducing cytokines IL-6 and IL-23 [141]. Treatment of CD4 $^+$  Th cells with 1,25(OH) $_2$ D under Th17-polarizing conditions (e.g., under the influence of IL-6 and TGF- $\beta$ 1) reduces the number of Th17 cells that develop [142]. VDR KO and vitamin D-deficient CD4 T cells overproduced IL-17 [143]. In addition, transfer of VDR KO CD8 $^+$  T cells to immunodeficient mice resulted in the rapid expansion of naïve CD8 $^+$  T cells that homed to the gut, produced IL-17, and induced IBD symptoms [144]. Enteric infection of vitamin D-deficient mice resulted in the delayed clearance of the infection that coincided with a delay in the generation of Th17 cells [127]. The induction of IL-22 and the inhibition of IL-17 help to resolve inflammation in the vitamin D-sufficient host [127]. Human peripheral blood mononuclear cells from IBD patients overproduce IL-17, and treating them with a vitamin D analog reduces the production of Th17 cells [145]. Vitamin D supports the induction of Th17 responses following infection. As the infection is controlled, vitamin D inhibits IL-17.

Vitamin D has been shown to control regulatory T cells including iNKT cells, Treg cells, and CD8 $\alpha\alpha$  T cells (Fig. 97.1). Expression of the VDR is required for normal development and function of iNKT cells [146]. 1,25(OH) $_2$ D increases iNKT cell cytokine production but has no effect on the numbers of iNKT cells [146]. VDR KO mice essentially have no functional iNKT cells [146]. The absence of iNKT cells is partially responsible for the susceptibility of VDR KO mice to dextran sodium sulfate (DSS)-induced colitis [147]. The ability of 1,25(OH) $_2$ D to suppress several experimental autoimmune diseases occurs via the induction of Treg cells [148]. 1,25(OH) $_2$ D has been shown in vitro to increase

Treg numbers [131,149]. However, VDR KO mice have normal numbers of thymic-derived Treg cells but fewer inducible Tregs [143]. Microbiota inducible T regs (FoxP3+/ROR $\gamma$ t+) in the colon are vitamin D targets. The FoxP3+/ROR $\gamma$ t+ T regs were fewer in the colons of D– than D+ mice [67]. Microbial transplants from D+ and D– mice into germ-free mice phenocopied the Treg cell differences in the recipients of D+ or D– microbiota [67]. The CD8 $\alpha\alpha$  T reg cells also require vitamin D for normal development. Vitamin D–deficient and VDR KO mice have half as many of the CD8 $\alpha\alpha$  T cells as their WT counterparts (Fig. 97.1; [150]). In addition, the CD8 $\alpha\alpha$  T cells from VDR KO mice are functionally impaired; they produce less IL-10 than those from the WT mice [150]. 1,25(OH) $_2$ D enhances the development and function of iNKT cells, Tregs, and CD8 $\alpha\alpha$  T cells. In the absence of vitamin D or the VDR, T regs, iNKT cells, and CD8 $\alpha\alpha$  T cells are fewer resulting in unregulated inflammation in the GI tract.

In summary, the vitamin D system (25(OH)D status, 1,25(OH) $_2$ D, and VDR expression) influences both the innate and acquired immune system in the gut. Vitamin D is essential for the generation of Th17 cells in the colon following enteric infection (Fig. 97.1). Following injury or infection, 1,25(OH) $_2$ D directly and indirectly inhibits pathogenic Th1 and Th17 cell responses (Fig. 97.1). In addition, vitamin D is required for iNKT cells, Treg cells, and CD8 $\alpha\alpha$  T cells to further suppress inflammation in the gastrointestinal tract (Fig. 97.1). When vitamin D is low, there is a limiting amount of 1,25(OH) $_2$ D, and therefore the VDR does not function. Low vitamin D leads to an absence of regulatory T cells and overactive Th1 and Th17 responses, resulting in excessive inflammation in the gastrointestinal tract and IBD (Fig. 97.1).

## 5. Experimental models of inflammatory bowel disease

Much of our knowledge about the mechanisms involved in IBD comes from experimental animal models of intestinal inflammation [111,151]. Although these models provide insight into the pathogenesis of IBD, there is not a mouse model that completely mimics either CD or UC. The aim of these models is to provide tools to researchers that allow for investigation into specific aspects of the diseases. There are several different animal models of IBD. Some experimental IBD models result spontaneously following KO of regulatory cytokines or cells, whereas others are induced following chemical injury, infection with enteric pathogens or immunization. In most of the models, there is interplay between the inability to control inflammation in the gut, the types and complexity of the bacteria in the gut, and loss of barrier function. The IL-2 KO mouse model

is unique in that germ-free mice develop colitis and are one example of an IBD model where the composition of the microbiota does not influence development of colitis [151]. Examination of several different experimental models of IBD can give a more comprehensive view of the effects of vitamin D on several important characteristics of the human disease.

Deletion of the suppressive cytokine IL-10 results in spontaneous intestinal inflammation. The intestinal inflammation that develops in IL-10 KO mice is because of an uncontrolled immune response to the commensal microflora in the intestine [12,152]. IL-10 KO mice that are either vitamin D deficient or VDR/IL-10 double KO develop severe fulminating colitis that is characterized by epithelial hyperplasia, significant weight loss, and premature mortality (Table 97.2; [125]). The severity of the inflammation is associated with an increase in the Th1 response to the bacteria in the intestine including increased IFN- $\gamma$ , IL-12, TNF- $\alpha$ , and IL-1 $\beta$  [152]. In contrast, feeding supplemental 1,25(OH) $_2$ D prevents inflammation in IL-10 KO mice and, when given after the onset of intestinal inflammation, can block the progression of the disease by reducing TNF- $\alpha$  through inhibition of several genes of the TNF- $\alpha$  pathway (Table 97.2; [128,129,157]).

A T cell-driven model of intestinal inflammation develops when naïve CD4 T cells are transferred to mice that lack T and B cells (recombination activating gene (Rag) KO). Rag KO mice that receive the transferred T cells develop a wasting disease as a result of increased inflammation in the small intestine and colon that is driven by uncontrolled Th1 and Th17 responses [158]. Transferring naïve VDR KO CD4 T cells to Rag KO mice increases the severity and induces a more rapid onset of the disease than WT CD4 T cells (Table 97.2; [125]). In addition, transfer of VDR KO CD8 $^+$ , but not WT CD8 $^+$  T cells, to Rag KO mice resulted in accumulation of disease inducing CD8 cells that produced IL-17 and IFN- $\gamma$  (Table 97.2; [144]). Cotransfer of T regs that were either FoxP3+ or CD8 $\alpha\alpha$ + suppressed IBD in these T cell transfer models [122,159]. VDR KO FoxP3+ Treg cells are as good as WT FoxP3+ Treg at suppressing IBD in the Rag KO transfer model [150]. Naïve VDR KO T cell transfer–induced colitis is more severe than colitis when naïve WT T cells are transferred.

Infection with *Citrobacter rodentium* (*C. rodentium*) has been used as a model of infection-induced colitis [111]. Host resistance to *C. rodentium* infection depends on early innate lymphoid cells (ILC)-3 cells that produce IL-22 and induce Th17 cells that clear the infection [111]. Following the induction of Th17 cells that clear the infection, FoxP3+/ROR $\gamma$ t+ T regs resolve inflammation. Vitamin D–deficient and VDR KO mice developed severe *C. rodentium* infection and colitis (Table 97.2; [127,155]). Vitamin D–insufficient mice

had more IL-17 in the colon but took longer than vitamin D-sufficient mice to clear the *C. rodentium* infection [127]. Reduced numbers of ILC3 and lower IL-22 were shown to be the cause of the early lethality in the vitamin D-deficient mice [127]. Treatment of mice with 1,25(OH)<sub>2</sub>D increased *C. rodentium* shedding but reduced colitis (Table 97.2; [156]). Vitamin D regulates the immune response and colitis following enteric infection.

Chemical treatment with either trinitrobenzene sulfonic acid (TNBS) or dextran sodium sulfate (DSS) is a way to induce inflammation in the gastrointestinal tract. TNBS and DSS colitis both are induced in mice without T and B cells, and therefore, these models are useful for studying innate immune dysfunction [151]. 1,25(OH)<sub>2</sub>D administration to mice was effective at reducing TNBS-induced colitis (Table 97.2; [141]). Vitamin D-deficient, Cyp27B1 KO, and VDR KO mice were more susceptible to colitis induced with DSS (Table 97.2; [38,147,153]). VDR KO mice had increased mortality following low levels of DSS; as a result of severe intestinal inflammation, loss of barrier function, and endotoxemia (Table 97.2; [106,147]). 1,25(OH)<sub>2</sub>D reduced the severity and improved recovery from DSS and TNBS-induced colitis (Table 97.2; [38,141]). In addition to the immunoregulatory functions of vitamin D, 1,25(OH)<sub>2</sub>D treatments protected mice from chemical injury to the gut, and in part, this was a result of improved barrier function in the presence of 1,25(OH)<sub>2</sub>D.

There is one model of IBD that failed to show beneficial effects of 1,25(OH)<sub>2</sub>D. IL-2 KO mice develop IBD because of an absence of Treg cells [154]. Interestingly the commensal microbiota are not important in the development of colitis in IL-2 KO mice [151]. 1,25(OH)<sub>2</sub>D treatment had no effect on IBD symptoms in the IL-2 KO mice (Table 97.2; [154]). The success of 1,25(OH)<sub>2</sub>D treatment in vivo in two chemical injury models, a T cell transfer model and IL-10 KO mice,

and lack of success in the IL-2 KO model give important insights into the mechanisms underlying the effects of vitamin D as a regulator of intestinal inflammation.

## 5.1 Vitamin D and the microbiota

Over the lifespan factors including early-life events, diet and antibiotic use affects the microbiota and impacts the development of immune-mediated disease. Vitamin D status has been shown to affect the microbiota [160]. Evidence to demonstrate an effect of vitamin D on the microbiota has been shown convincingly in rodents that are on identical diets that differ only in the vitamin D content. Vitamin D-deficient mice have higher Firmicutes and lower numbers of short-chain fatty acid producing bacteria than vitamin D-sufficient mice [67]. Transplantation of the microbiota was able to reproduce the effects of vitamin D to increase the FoxP3<sup>+</sup>/RORγt T regs [67]. Vitamin D-sufficient mice had lower numbers of the Proteobacter phyla and Helicobacter family members than vitamin D-deficient mice (Fig. 97.1; [38]). 1,25(OH)<sub>2</sub>D treatment, of vitamin D-deficient mice, reduced Helicobacter numbers in the mice [38]. Two human trials that supplemented vitamin D in healthy individuals and raised serum 25(OH)D levels were done [161,162]. One trial failed to show significant effects on the microbiota [161,162], while the other showed lower Proteobacteria phyla members with vitamin D intervention [163]. The effects of vitamin D on the microbiota likely depend on the diet, vitamin D status, and other parameters that are difficult to control in human trials. In addition, the effects of vitamin D on the microbiome of a healthy individual may be different than the effect in a patient with dysbiosis. Determining the effectiveness of vitamin D interventions on the microbiota in humans depends on the health and diet of the participants.

Experimentally, the effects of vitamin D on the microbiota have been done using germ-free mice. Germ-free mice have dense bones and fewer osteoclasts than mice with an intact microbiome [164]. The metabolism of vitamin D in germ-free mice was disrupted and mice were hypocalcemic, with very high fibroblast growth factor (FGF)-23, and low serum 25(OH)D/1,25(OH)<sub>2</sub>D levels [165]. Microbial colonization with commensals resulted in mild inflammation followed by inhibition of FGF-23 and then normalization of the serum 25(OH)D levels [165]. Infection of the germ-free mice with a pathogen, reduced serum 25(OH)D levels further, before eventually resolving the infection and reinstating homeostasis and raising serum 25(OH)D levels [165]. In addition, antibiotic disruption of the microbiota increased FGF-23 and disrupted vitamin D metabolism [166]. The microbiota and antibiotics regulate inflammation and FGF-23 levels that control vitamin D metabolism and calcium homeostasis.

Mice and humans with IBD have dysbiosis. The effects of vitamin D to improve experimental colitis are linked to the effects of vitamin D on the microbiota. Vitamin D-deficient and VDR KO mice had microbial dysbiosis that contributed to increased susceptibility to DSS colitis [38]. Antibiotic treatment of the mice eliminated the effect of vitamin D/VDR deficiency on susceptibility to DSS colitis [38]. The inhibition of pathogenic *Helicobacter* bacteria, by either 1,25(OH)<sub>2</sub>D or antibiotics treatment, corresponded with protection from DSS colitis [38]. VDR KO mice or vitamin D-deficient mice had increased barrier dysfunction, dysbiosis of the microbiota, and more intestinal inflammation following infection [155,167,168]. Of note the composition of the commensal flora in vitamin D-deficient or VDR KO mice resembled the dysbiosis noted in IBD patients with fewer commensal from the Firmicutes phyla and higher potentially pathogenic Proteobacteria and Actinobacteria phyla members (Fig. 97.1; [38,107]). High-dose vitamin D treatment reduced Proteobacteria phyla members [163]. In three participants that were *Helicobacter pylori* positive, there was a reduction in *Helicobacter* at the end of the 8 week vitamin D intervention [163]. Clinical trials of vitamin D to manipulate the microbiota were somewhat effective in patients with multiple sclerosis, cystic fibrosis, diabetes, CD, and UC [161,162,169–172]. Vitamin D has been shown to increase Bacteroidetes and decrease Firmicutes [161,162,169–172]. The human and mouse data point to vitamin D regulation of the commensal microbiota that helps to maintain gastrointestinal homeostasis.

## 6. Current treatments for inflammatory bowel disease

There is no cure for IBD. Immunosuppressive drugs are used to induce remission but are not used as

maintenance drugs because of their toxicity and side effects. For maintenance, there are a number of different options ranging from immunomodulators to biological therapies. The use of these newer treatments has resulted in the improved quality of life for patients living with IBD. 5-Aminosalicylic acid (5-ASA) and corticosteroids are the standard first-line therapies for inducing remission in patients with mild to moderate IBD. 5-ASA has been shown to inhibit the synthesis of prostaglandin, leukotrienes, and IL-1 $\beta$  and to suppress the activation of NF- $\kappa$ B by TNF- $\alpha$  and IL-1 [173]. 5-ASA is a broad antiinflammatory agent that has been shown to be effective for treating mild to moderate UC but is less effective for CD [174]. Glucocorticoids, such as prednisone, nonspecifically suppress the immune system and are used to treat moderate to severe CD and UC. Treatment with glucocorticoids is an effective way of inducing remission; however, prolonged use results in steroid dependence or resistance [175]. Although glucocorticoids and 5-ASA are effective treatments to induce remission, not all patients respond. Failure to respond to drug therapy is associated with a worse prognosis, including increased risk of surgery, risk of disability, and an increased risk of infection.

The development of other immunosuppressive drugs has improved treatment for maintaining remission of IBD and has been shown to be useful for limiting long-term use of glucocorticoids [6,176]. Azathioprine, methotrexate, and cyclosporin suppress inflammation by limiting T cell activity. It has been demonstrated that azathioprine treatment is effective for inducing remission in patients with mild IBD and maintaining remission [177]. Methotrexate inhibits the enzymes involved in the nucleoside synthesis and consequently suppresses T cell activation and proliferation and inhibits the expression of adhesion molecules [177]. Treatment with methotrexate is effective in CD but less so for UC [178]. Cyclosporin is a widely used immunosuppressant that inhibits T cell activation by suppressing calcium activation pathway via the inhibition of calcineurin [179]. Cyclosporin has been shown to be effective for treating patients with severe, steroid-refractory UC but has not proven to be effective in patients with severe CD [180].

Within the past 15 years, a number of new biological therapies have been developed and found to be useful to treat IBD. Biologicals target specific aspects of the immune response that contribute to intestinal inflammation. Infliximab (Remicade) and adalimumab (Humira) are some of the first biologics that have been shown to be effective therapy options for patients with IBD [181]. Infliximab and adalimumab are both humanized antibodies that block the activity of TNF- $\alpha$ . These TNF- $\alpha$  blocking drugs were first shown to be effective in patients with arthritis. In 1998, the FDA approved the use of infliximab to treat patients with moderately and severely active IBD who do not respond to conventional

treatment. One of the main complications that exist with the use of this family of drugs is that patients can develop specific immunity against the therapy and stop responding [182]. Since the introduction of the TNF blockers, there have been many other biologicals developed that target other inflammatory cytokines or the cytokine receptors including those for IL-12, IFN- $\gamma$ , and IL-6 [183]. There are now biologicals that antagonize T cells and some that target leukocyte migration [183,184]. These treatments are very expensive, and it is estimated that the use of biologicals to treat IBD results in healthcare costs of more than \$200 billion worldwide [185]. There are many drawbacks to the biologics including expense, required medical personnel to administer, and increased susceptibility to opportunistic infection and cancer. Presently, patients with IBD require lifelong treatment. Because of the expense and risks of all of the current therapies, IBD researchers and patients are interested in exploring alternative strategies to limit intestinal inflammation.

### 6.1 Microbial interventions and IBD

Strategies to modify the microbiota and correct dysbiosis in patients with IBD are of recent interest. One approach would be to use antibiotics to eliminate potential pathogens. Oral antibiotic treatment can be beneficial in models of IBD by eliminating bacteria that are inducing an inappropriate immune response [186]. The use of antibiotics in one study was associated with an increased risk of inflammation, presumably because good microbial flora was eliminated in the gastrointestinal tract [32]. Antibiotic resistance would be an additional barrier to using antibiotics for long-term treatment of IBD. A different approach would involve the transplantation of microbiota from a healthy individual (fecal microbial transplantation [FMT]) to replace the microbiota. FMT has been shown to be effective for the treatment for *Clostridioides difficile* (*C. difficile*) infection [187]. Interestingly, patients with *C. difficile* infection have dysbiosis that resembles vitamin D deficiency; high Proteobacteria and high Firmicutes/Bacteroidetes ratios (Fig. 97.1; [161–163,169–172,188]). Vitamin D-supplemented mothers were less likely to have infants that developed *C. difficile* infections [189]. While FMT for both CD and UC has shown some success, the longevity of the microbial changes or the optimal donor microbes are still not well described [39,40]. Alternatively, probiotics contain viable, defined microorganisms that, when administered in adequate amounts, alter the microflora of the host [190,191]. Probiotics have been shown to have some effectiveness in IBD

patients to induce or maintain remission [191]. Dietary treatments can also shift the microbiota [190]. The production of short-chain fatty acids by the microbial digestion of fiber induces regulatory T cells and suppresses experimental colitis [59,60]. Changes in the microbiota induced through FMT or probiotics may be short lived without additional changes in diet or lifestyle that impact the microbiome. If found to be effective dietary interventions, probiotics hold the promise of treatments that have few side effects and could be used to augment or even replace some of the maintenance therapies for IBD patients.

## 7. Vitamin D as a treatment option for inflammatory bowel disease

Vitamin D and its active metabolites and analogs could be a safe and effective adjunct to the therapies available to treat or prevent IBD. Two small open label trials (one with alfalcidol [192], and one with vitamin D [94]) showed a decrease in CD activity index with vitamin D intervention. Jorgensen showed in a randomized double-blind placebo-controlled study that vitamin D intervention insignificantly ( $P = .0567$ ) reduced the relapse rate in patients with CD [193]. Vitamin D interventions of 2000 IU for 6 months reduced the IBD activity score in children [194]. A recent metaanalysis of 18 randomized controlled trials also indicated that vitamin D interventions improved vitamin D status and prevented relapse [195]. Several issues [196] still need to be resolved for better vitamin D interventions, including the following: (1) What is the appropriate dose and frequency of delivery for the vitamin D intervention? (2) Does it matter what other therapies a patient is on? (3) Can patients with either UC or CD or both benefit? (4) What is the target 25(OH)D levels? (5) Will there be an effect of vitamin D on severe UC or CD? 1,25(OH) $_2$ D or analogs of 1,25(OH) $_2$ D have been shown to be effective treatments of experimental IBD. It is possible that 1,25(OH) $_2$ D rather than vitamin D itself could suppress mild to moderate IBD and perhaps be a glucocorticoid-sparing drug. The benefits of vitamin D in IBD could be multiple, including a reduction in inflammation, alterations in the commensal microbiota and the decreased severity of the disease as well as resolution of secondary hyperparathyroidism and improvement in BMD [192]. However, evaluation of 25(OH)D status has not been established as standard of care in patients with IBD. Even when vitamin D deficiency is detected, there are no established guidelines for treatment in children or adult IBD patients [78].

## 8. Conclusions

Vitamin D is one of several environmental factors that impact the development of UC and CD. Vitamin D-deficient mice develop severe forms of experimental IBD that can be suppressed by treatment with vitamin D/1,25(OH)<sub>2</sub>D. The targets of vitamin D that have been identified in IBD include reductions in pathogenic T cells, induction of regulatory T cells, improved barrier function, induction of pathogen recognition receptors in innate immune cells, and alterations in the microbiota. There is some clinical data that suggests that improving vitamin D status would benefit patients with IBD especially CD. More work needs to be done to understand the mechanisms by which vitamin D maintains gastrointestinal homeostasis and how to best translate the current findings to treating and/or preventing IBD.

## 9. Summary points

- Vitamin D status and the microbiota are two environmental factors that impact the development of IBD.
- Vitamin D or 1,25(OH)<sub>2</sub>D treatments reduced experimental colitis in multiple different animal models.
- Vitamin D insufficiency is associated with increased UC and CD severity.
- Vitamin D regulates innate and acquired immunity to control inflammation in the gastrointestinal tract.
- The beneficial effects of vitamin D in IBD are due in part to the regulation of the gut microbiota.
- Vitamin D interventions might be effective, safe, low-cost therapies that alter the microbiota and improve gastrointestinal health.

# Vitamin D and tuberculosis

Adrian R. Martineau

Centre for Immunobiology, Blizard Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, United Kingdom

## OBJECTIVES

- To describe the human immune response to *Mycobacterium tuberculosis*, and how it is modulated by vitamin D.
- To review historical evidence relating to a potential role for vitamin D supplementation in tuberculosis prevention or treatment.
- To summarize evidence from observational epidemiological studies and randomized controlled trials of vitamin D for the prevention or treatment of tuberculosis infection or disease.

## 1. Introduction

Tuberculosis (TB) is caused by infection with the gram-positive acid-fast bacterium *Mycobacterium tuberculosis* (MTB), which was first described by Robert Koch in 1882 [1]. The disease has troubled humans for millennia [2] and is a major global public health problem today. The global prevalence of latent MTB infection (LTBI) has been estimated at 23% [3] and this carries a 5%–20% lifetime risk of reactivation disease in people who are not infected with human immunodeficiency virus (HIV) [4]; reactivation rates higher than 10% per annum have been reported in HIV-infected people [5]. The World Health Organization (WHO) estimates that in 2021 there were 10.6 million incident cases of active TB, and 1.6 million deaths from TB worldwide. This represents a stagnation in the annual decline in TB incidence, and an increase in estimated TB deaths

compared with recent years, both of which have been attributed to adverse impacts of the COVID-19 pandemic on TB control programs [6].

Global efforts to control the TB epidemic have focused on prevention of active disease by vaccination with *Mycobacterium bovis* Bacille Calmette Guérin (BCG) and treatment of LTBI and active TB with combination antimicrobial therapy [7]. The protection imparted by BCG vaccine against TB is highly variable and has been reported to vary from nil to 94%, with greater protection observed at higher latitudes [8]. Treatment of LTBI with isoniazid reduces risk of reactivation disease both in the absence and in the presence of HIV infection [9,10]. Treatment of active TB with conventional short-course chemotherapy (comprising rifampicin, isoniazid, pyrazinamide, and ethambutol for 2 months, followed by rifampicin and isoniazid for 4 months) is effective for the treatment of drug-sensitive disease; however, a significant proportion of patients do not complete treatment [11], resulting in the emergence of drug-resistant strains, which require prolonged therapy with second-line antimicrobial therapy and which cause significant morbidity and mortality [12]. The development of new agents to prevent acquisition or reactivation of LTBI and to allow shortening of antimicrobial therapy regimens for active TB without loss of efficacy is a research priority. This chapter reviews evidence from studies conducted both in vitro and in vivo investigating mechanisms by which vitamin D metabolites modulate immune responses to MTB, and exploring whether vitamin D may have a role in the prevention and treatment of TB. I begin by reviewing in vitro studies that have contributed to the current understanding of the immune response in tuberculosis.

## 2. The immune response in tuberculosis

MTB may enter the human host by inhalation, ingestion, or inoculation; of these routes, inhalation is the most common. Individuals with infectious pulmonary TB expectorate an aerosol of droplet nuclei 1–2  $\mu\text{m}$  in size containing the pathogen, which enter the alveoli where they are phagocytosed by alveolar macrophages, neutrophils, or dendritic cells. Phagocytosis is an active process in which bound mycobacteria are surrounded by phagocyte membrane and then internalized in membrane-enclosed vesicles called phagosomes. Phagosomes are then acidified, and fuse with lysosomes, membrane-enclosed granules containing antimicrobial peptides and hydrolytic enzymes; phagolysosomal fusion is facilitated by the induction of autophagy, a catalytic process involving degradation of cytosolic contents. The importance of this process in host defense against MTB is highlighted by the observation that inhibition of phagosome–lysosome fusion is a key mycobacterial defense strategy [13], which is mediated by the generation of ammonia by virulent mycobacteria [14] and by retention of tryptophan aspartate-containing coat protein (TACO) in the phagosomal membrane [15]. Activation of phagocytic cells also results in induction of innate antimicrobial responses, such as the generation of reactive nitrogen and oxygen intermediates, induction of antimicrobial peptides, production of pro-inflammatory cytokines such as tumor necrosis factor (TNF) and interleukin-12 (IL-12), and measures to limit availability of lipid droplets to the pathogen [16]. MTB may also be phagocytosed by respiratory epithelial cells, which exert anti-mycobacterial activity via induction of antimicrobial peptides [17] (see Chapters 94 and 95 for more detailed information on this topic).

If innate antimicrobial responses are non-sterilizing, antigen-presenting cells migrate from the lung via the lymph ducts to the lymph node, where presentation of mycobacterial antigens on major histocompatibility complex class II (MHC II) molecules leads to activation and expansion of antigen-specific T cell populations that mediate the adaptive immune response. Activated T cells migrate back to the site of infection in the lung via the bloodstream, where they surround infected macrophages to form granulomata. Activated T cells interact with infected macrophages within the granuloma: CD4<sup>+</sup> T cells secrete cytokines such as interferon- $\gamma$  (IFN- $\gamma$ ), which orchestrate the immune response to the pathogen and enhance macrophage activation, while CD8<sup>+</sup> T cells may kill infected macrophages [18] (see Chapters 94–96). The critical importance of TNF, IL-12, and IFN- $\gamma$  in the anti-mycobacterial immune response is illustrated by clinical observations that individuals with defects in these

pathways have heightened susceptibility to mycobacterial infection [19–21]. However, active tuberculosis is associated with expression of type I interferons [22], which may suppress IFN- $\gamma$ -inducible anti-mycobacterial responses [23].

The interactions between host and pathogen described before have several potential outcomes. It is well recognized that a significant proportion of individuals exposed to infectious cases of TB do not subsequently develop evidence of an adaptive response to MTB [24], suggesting that innate mechanisms may be effective in eliminating infection before initiation of the adaptive immune response [25]. A second group of individuals may develop evidence of an early adaptive response (i.e., MTB antigen-stimulated T cell production of IFN- $\gamma$ ), which subsequently reverts from positive to negative [26]: this may signify successful elimination of infection following initiation of an adaptive response. A third group may develop persistent evidence of T cell priming without developing clinical or radiological features of active disease; these individuals are thought to have LTBI, with MTB held in a state of non-replicating persistence. Individuals with LTBI may remain asymptomatic for life or may subsequently progress to develop active disease (secondary TB) [27]. Finally, in some individuals, the immune response does not restrict growth of the organism, and active disease develops shortly after infection (primary TB) [28].

## 3. Influence of vitamin D on the immune response to MTB

Humans acquire vitamin D via cutaneous synthesis as a result of the action of solar ultraviolet B radiation on 7-dehydrocholesterol in the skin, or from the diet, principally by consumption of oily fish or dietary supplements (see Chapter 3 and Chapters 55–58). Vitamin D from either source is metabolized by the liver to form 25-hydroxyvitamin D (25(OH)D), the major circulating metabolite of vitamin D whose serum concentration is used to define vitamin D status. 25(OH)D circulates bound to vitamin D-binding protein (DBP) and is metabolized by the enzyme 25(OH)D-1 $\alpha$ -hydroxylase (CYP27B1), expressed in the kidney, as well as in leukocytes, gastrointestinal tract, skin, vascular endothelium, and placenta to form 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D), the steroid hormone, and active metabolite of vitamin D. 1,25(OH)<sub>2</sub>D induces biological actions by ligating vitamin D receptor (VDR). Both 1,25(OH)<sub>2</sub>D and 25(OH)D are catabolized by the 24-hydroxylase enzyme CYP24A1 to form the relatively biologically inactive metabolites 1,24,25-trihydroxyvitamin D and 24,25-dihydroxyvitamin D, respectively.

With the exception of two reports [29,30], vitamin D and its metabolites have not been shown to possess anti-mycobacterial activity in the absence of cells. However, 1,25(OH)<sub>2</sub>D has long been recognized to induce anti-mycobacterial activity in vitro in mononuclear phagocytes [31]. Its precursor 25(OH)D has also been shown to support induction of innate anti-mycobacterial responses [32], as illustrated in Fig. 98.1. Ligation of macrophage Toll-like receptor (TLR) 2/1 heterodimers by mycobacterial lipoprotein induces expression of VDR and CYP27B1 [33,34]. CYP27B1 is also induced by IL-15 [34] (produced by peripheral blood monocytes in response to TLR2/1 stimulation), CD40 ligand [35], and IFN- $\gamma$  [36] (produced by CD4 + T helper type 1 [Th1] cells): indeed, human macrophages require 25(OH)D for induction of IFN- $\gamma$ -mediated anti-mycobacterial activity [32]. Induction of CYP27B1 and VDR by IFN- $\gamma$  is blocked by IFN- $\beta$  and IL-10 [23]. Because extra-renal CYP27B1 follows first order kinetics, the rate at which it synthesizes 1,25(OH)<sub>2</sub>D depends on availability of 25(OH)D substrate [37] (see Chapter 9). Orally ingested vitamin D is freely converted to 25(OH)D [38], and this provides the rationale for administering “parent” vitamin D to induce anti-mycobacterial responses at the site of infection.

1,25(OH)<sub>2</sub>D modulates immune responses by ligating membrane VDR to induce rapid effects (within minutes), or nuclear VDR to induce genomic effects (within

hours) [39]. Experiments using selective agonists and antagonists of these two receptors indicate that ligation of nuclear VDR is both necessary and sufficient for induction of anti-mycobacterial responses by 1,25(OH)<sub>2</sub>D in vitro [40]. 1,25(OH)<sub>2</sub>D modulates the host response to mycobacterial infection by pleiotropic mechanisms including the induction of reactive nitrogen and oxygen intermediates [41,42], down-regulation of TACO [43], promotion of phagolysosome fusion [44], and induction of antimicrobial peptides including cathelicidin (LL-37) [33,40] and (in synergy with IL-1 $\beta$ ) human beta defensin 2 [45]. Cathelicidin LL-37 possesses anti-mycobacterial activity [25,33] and induces autophagy [46,47], which inhibits replication of both MTB and HIV in co-infected macrophages [48]. 1,25(OH)<sub>2</sub>D-induced anti-mycobacterial activity has been reported to be dependent on expression of *hCAP18*, the gene encoding the parent molecule from which LL-37 is cleaved [49], and potentiated by co-culture with the aromatic fatty acid phenylbutyrate [50,51]. 1,25(OH)<sub>2</sub>D has also been reported to enhance expression and secretion of IL-1 $\beta$  by MTB-infected macrophages, which induces anti-mycobacterial activity in respiratory epithelial cells via induction of human  $\beta$ -defensin 2 [17].

In addition to inducing innate antimicrobial responses, 1,25(OH)<sub>2</sub>D modulates macrophage, dendritic cell, and T cell function to regulate innate and adaptive immune responses to infection. In the macrophage, 1,25(OH)<sub>2</sub>D directly regulates its own synthesis and catabolism via inhibition of *CYP27B1* and induction of *CYP24A1*, respectively; it also downregulates expression of TLR2/1 [52], TNF [40], and matrix metalloproteinase (MMP) enzymes that are implicated in the pathogenesis of pulmonary cavitation [53], as well as downregulating PPAR- $\gamma$  to abrogate infection-induced accumulation of lipid droplets required for intracellular growth of MTB [54] (Fig. 98.2). 1,25(OH)<sub>2</sub>D also inhibits dendritic cell maturation [55], downregulates MHC class II expression, inhibits secretion of IL-12, and induces secretion of IL-10 [40]; together, these actions skew development of null T helper cells away from a Th1 phenotype and toward T helper type 2 (Th2) and T regulatory cell profiles [55–57] (Fig. 98.3). Finally, in the granuloma, 1,25(OH)<sub>2</sub>D attenuates antigen presentation via inhibition of macrophage MHC class II expression and directly modulates T helper cell cytokine secretion, stimulating production of IL-4 from Th2 cells and inhibiting IFN- $\gamma$  production from Th1 cells. Since IL-4 induces catabolism of 25(OH)D in a CYP24A1-dependent manner [58], and IFN- $\gamma$  induces *CYP27B1* expression [36], this represents another negative feedback loop via which 1,25(OH)<sub>2</sub>D regulates its own concentration at the site of mycobacterial infection (Fig. 98.4). Further discussion of the effects of vitamin D on immune responses to bacterial infection can be found in Chapter 94.

**FIGURE 98.1** 25-hydroxyvitamin D supports macrophage TLR ligand-induced innate antimicrobial responses. Mycobacterial lipoproteins ligate TLR2/1 heterodimers on the macrophage surface, leading to induction of *CYP27B1* and VDR. IL-15, CD40L and IFN- $\gamma$  also induce *CYP27B1*, but this is blocked by IFN- $\beta$  and IL-10. In the presence of adequate 25(OH)D substrate, *CYP27B1* synthesizes 1,25(OH)<sub>2</sub>D, which ligates VDR to initiate pleiotropic antimicrobial responses (including induction of reactive nitrogen and oxygen intermediates, antimicrobial peptides, and autophagy) and secretion of IL-1 $\beta$ .

**FIGURE 98.2** 1,25(OH)<sub>2</sub>D regulates innate inflammatory responses to mycobacterial infection. 1,25(OH)<sub>2</sub>D downregulates expression of TLR2/1, suppresses secretion of TNF and MMP enzymes implicated in the pathogenesis of pulmonary cavitation, and inhibits dendritic cell maturation. It also downregulates PPAR-γ to abrogate infection-induced accumulation of lipid droplets required for intracellular growth of *Mycobacterium tuberculosis*. 1,25(OH)<sub>2</sub>D directly regulates its own synthesis and catabolism via inhibition of CYP27B1 and induction of CYP24A1, respectively. Arrows represent stimulatory actions, and bars represent inhibitory actions.

**FIGURE 98.3** 1,25(OH)<sub>2</sub>D influences T helper cell profile. In secondary lymphoid tissue, 1,25(OH)<sub>2</sub>D acts on the dendritic cell to enhance secretion of IL-10 while suppressing secretion of IL-12 and expression of MHC class II. Together, these actions favor development of null T helper cells toward Th2 and T regulatory phenotypes, and away from Th1 and Th17 phenotypes. Arrows represent stimulatory actions, and bars represent inhibitory actions.

Given the suppressive effects of 1,25(OH)<sub>2</sub>D on Th1 responses reviewed before, and the clinical observation that such responses are required for host defense against intra-cellular pathogens, there is clearly potential for in vivo vitamin D supplementation to attenuate anti-mycobacterial responses as well as to enhance them. However, while abrogation of the IL-12 and IFN-γ pathways clearly results in exquisite susceptibility to

mycobacterial infection [20,21], it does not necessarily follow that partial attenuation of these responses will lead to impaired protection against, or resolution of, TB. In active disease, in particular, Th1 cytokines may cause immunopathology [59]; an immunomodulatory agent with the ability to induce antimicrobial activity and inhibit Th1-induced immunopathology simultaneously might therefore have potential as an adjunct to

**FIGURE 98.4** 1,25(OH)<sub>2</sub>D modulates adaptive responses to mycobacterial infection in the granuloma. 1,25(OH)<sub>2</sub>D stimulates secretion of IL-4 from Th2 cells and inhibits secretion of IFN-γ from Th1 cells to regulate its concentration at the site of mycobacterial infection. Arrows represent stimulatory actions, and bars represent inhibitory actions.

anti-tuberculous therapy, for example. Only clinical studies can resolve the question of whether stimulatory or suppressive immunomodulatory actions of vitamin D are dominant in vivo. A review of such studies follows, beginning with a consideration of the historical literature.

#### 4. Historical studies

The clinical features of vitamin D deficiency were first described in 1651, when Glisson, Bate, and Regemorter published “A treatise of the rickets: being a disease common to children” [60]. In addition to noting the classical musculoskeletal features of rickets, the authors made the following observation from an autopsy of an infant with the condition: “One amongst us doth attest, that he saw glandulous knobs and bunches so numerous that they seemed to equalise, if not exceed, the magnitude of the lungs themselves; they were situated between the lungs and the mediastinum ... and were extended from the Canel bone to the Diaphragma.” TB is a well-recognized cause of mediastinal lymphadenopathy in children [61], and it is interesting to speculate whether this represents the earliest case report of TB associated with vitamin D deficiency.

Some 200 years later, physicians at the Hospital for Consumption and Diseases of the Chest, Brompton, London, conducted an intervention study to evaluate the effects of administering cod liver oil (which contains high concentrations of both vitamin D and vitamin A) to

patients with “pulmonary consumption.” A total of 542 patients were treated with thrice daily doses of cod liver oil ranging from 3.6 to 42 mL, and their clinical outcomes were compared with those of a control group of 542 patients who did not receive the oil: 19% of patients receiving cod liver oil died, compared with 33% of those who did not receive it. It was concluded that “Cod Liver Oil possesses the property of controlling Pulmonary Consumption to a greater extent than any other agent hitherto tried” [62]. This report represents some of the earliest evidence that administration of a preparation containing vitamin D improved clinical outcome in patients with TB, although it should be noted that allocation was not randomized, bacteriological confirmation of diagnosis was lacking (the study predated Koch’s discovery of MTB by more than 3 decades), and that any beneficial effects of cod liver oil may be attributable to its content of vitamin A rather than vitamin D [63]. The first TB sanatorium was opened in Gorborsdorf, Germany (today Sokolowsko, Poland) in 1859, and heliotherapy (exposure of TB patients to the sun, thereby promoting cutaneous synthesis of vitamin D) subsequently became common practice and was credited with improvements in clinical outcome in many cases [64]. In 1903, Niels Finsen was awarded the Nobel Prize in Physiology or Medicine for his discovery that short-wave ultraviolet light was effective in the treatment of cutaneous TB [65]. While it is possible that these effects were mediated by induction of cutaneous vitamin D synthesis, it should be noted that ultraviolet irradiation modulates immune responses via vitamin D-independent pathways [66] and that it also directly inactivates MTB [67].

In 1914, McCollum and coworkers subsequently conducted a series of experiments, leading to the discovery of vitamin D. They isolated a substance from butterfat, necessary for prevention of xerophthalmia in rats, and named it “fat-soluble factor” A [68]. They subsequently reported that heated oxidized cod liver oil could not prevent xerophthalmia but could cure rickets in rats and concluded that “fat-soluble factor A” consisted of two entities, one that could prevent xerophthalmia (subsequently called vitamin A), and one that cured rickets (subsequently called vitamin D, as the terms vitamin B and vitamin C had already been coined) [69]. Vitamin D<sub>2</sub> was purified and crystallized in 1931 [70], and Charpy subsequently pioneered the use of pharmacologic doses ( $\geq 1.25$  mg or 50,000 IU daily) of vitamin D<sub>2</sub> to treat cutaneous TB [71]. Vitamin D<sub>2</sub> was also used to treat pulmonary TB, both as a single agent and, following the introduction of effective anti-tuberculous chemotherapy, as an adjunct to antibiotic treatment. Case series reporting this practice are summarized in Table 98.1: broadly, those in which doses of vitamin D  $\geq 1.25$  mg/day ( $\geq 50,000$  IU/day) had been

**TABLE 98.1** Case series investigating effects of administering vitamin D to patients with tuberculosis.

References	Participants setting	Dose of vitamin D	Concurrent antimicrobial treatment	Therapeutic response	Adverse events
Brincourt et al., [72]	" > 100" patients with PTB, France	600,000 IU D2 every 10 days for up to 4 months (maximum dose 7.2M IU)	Antibiotic treatment—not specified	Rapid liquefaction of caseating necrosis; decreased fibrotic sequelae	One patient developed hypercalcemia after 7.2M IU total dose; nephrocalcinosis did not ensue
Trautwein et al., [73]	35 patients with PTB and cutaneous TB, Germany	200,000 IU D2 3 × / week	PAS or TB.I	19/35 made "good/very good response," 10/35 "some/temporary" response	4/35 developed hypercalcemia (> 3 mmol/L)
Fielding et al., [74]	7 adult patients with PTB, United Kingdom	600,000 IU D2 IM weekly for 3 doses, fortnightly for 4 weeks, monthly for 4 months (total dose 5.4M IU)	Streptomycin and PAS	"Cavitation reduced" in 6/7; 1/7 (with streptomycin-resistant disease) deteriorated	No toxic effects attributed to calciferol; anorexia and vomiting "in some cases" attributed to PAS
Gerecke et al., [75]	81 pts with PTB, Germany	40,000 IU daily	With or without TB.I	Four cases with combination showed response; none taking vitamin D alone showed a response	Not reported
Sude et al., [76]	9 patients with PTB, Germany	600,000 IU D2 3 × / week for 1st week, 2 × /week in 2nd to 4th weeks, then weekly	No	None improved; 5 deteriorated	2 patients developed hypertension; 1 patient discontinued vitamin D due to symptomatic hypercalcemia
Jongmans et al., [77]	123 patients with PTB, Holland	90,000 IU D2 po daily for up to 12 months	No	Not reported	5 patients experienced exacerbation of symptoms
Ianovskaya et al., [78]	78 patients with PTB and cutaneous TB, Russia	50,000 to 100,000 IU D2 po daily	No	42/78 improved; 28/78 unchanged; 8/78 deteriorated	16 of the 42 patients who improved experienced exacerbation of symptoms
Seeber et al., [79]	28 patients with PTB	20,000IU D2 daily, increasing to 40,000 IU daily; total dose 6M IU	No	12/28 improved; 13/28 unchanged; 3/28 deteriorated	Not reported
Winterberg et al., [80]	52 patients with PTB, Germany	400,000 IU D2 every 5–10 days	Not reported	44/52 improved	Not reported
Feeny et al., [81] English.	21 patients with PTB, United Kingdom	25,000 IU D2 daily po, increasing to 100,000 IU/day	3 mg vitamin B1 daily po	ESR up in 12/21, down in 5/21. 16/21 sputum positive before and after treatment; 2 converted positive to negative; 2 remained negative; 1 produced no sputum	Headache in 7/21; nausea in 16/21; vomiting in 4/21

administered reported beneficial effects (despite the lack of control groups), and occasional hypercalcemia was observed. Hypercalcemia had been recognized to associate with TB since 1931, in both the presence and absence of vitamin D supplementation [82]. Indeed, a case report of hypercalcemia arising in a TB patient with end-stage renal disease, associated with elevated circulating concentrations of  $1,25(\text{OH})_2\text{D}$ , led to the discovery of dysregulated CYP27B1 activity in patients with TB—one of the first examples of extra-renal vitamin D metabolism to be recognized beyond sarcoidosis [83].

Taken together, evidence from the in vitro literature and historical studies suggests four potential clinical applications of vitamin D in TB control: prevention of MTB infection, prevention of LTBI reactivation, enhancement of response to antimicrobial therapy, and prevention of recurrent disease (Fig. 98.5). I will now review clinical studies from the modern era, classified according to the outcome measure or endpoint studied, namely, acquisition of MTB infection, incident active tuberculosis (disease), and response to antimicrobial therapy for active disease (treatment studies). In each case, observational and intervention studies will be reviewed in turn.

## 5. Studies with MTB infection as an end point

### 5.1 Observational studies

Cross-sectional and case–control studies conducted in Australia [84], Italy [85], Gambia [86], Mongolia [87,88], and the United States [89] have all reported independent associations between lower circulating  $25(\text{OH})\text{D}$  concentrations and increased risk of MTB infection, although a study in Brazil found no such association [90]. Three cohort studies in Spain both found an association between low serum  $25(\text{OH})\text{D}$  concentrations and increased risk of tuberculin skin test conversion following exposure to a case of infectious TB [91–93], while a population-based longitudinal study in South Africa found an association between vitamin D deficiency in early infancy and increased risk of tuberculin skin test conversion by the age of 2 years [94]. Another cohort study, conducted in Peru, has reported a temporal association between vitamin D deficiency and incident MTB infection in a cohort of TB contacts: a midwinter peak in vitamin D deficiency was followed 6 weeks later by a late-winter peak in tuberculin skin test positivity and 12 weeks after that by an early-summer peak in QuantiFERON positivity [95].

**FIGURE 98.5** Potential roles for vitamin D in the prevention and treatment of tuberculosis. Enhancement of the immune response to *Mycobacterium tuberculosis* by means of vitamin D supplementation might prevent acquisition of latent TB infection in exposed individuals (A) Prevent reactivation of latent TB infection to reduce incidence of active disease (B) Enhance response to antibiotic therapy in active disease, to improve outcome or to allow shortening of antibiotic treatment regimens (C) Or prevent recurrent disease in those who have recovered from a previous episode (D) Arrows represent disease progression, and bars represent potential inhibitory/therapeutic actions of vitamin D. Estimated numbers from the WHO Global Tuberculosis Report, 2022.

## 5.2 Intervention studies

Building on positive findings from a proof-of-concept study showing that vitamin D supplementation augmented anti-mycobacterial immunity in whole blood [96], three randomized controlled trials (RCTs) investigating the influence of vitamin D supplementation on resistance to MTB infection have been conducted to date [97–99]. Ganmaa and colleagues first conducted a pilot study, in which they randomized 120 Mongolian schoolchildren aged 12–15 years to receive a daily oral dose of 800 IU vitamin D<sub>3</sub> or placebo for a period of 6 months. Tuberculin skin tests were performed at baseline and at the end of the trial: these converted from negative to positive in 11% of children receiving vitamin D vs. 27% of those receiving placebo (RR: 0.41; 95% CI: 0.16, 1.09;  $P = .06$ ). These positive results led to conduct a phase 3 RCT of vitamin D for the prevention of MTB infection in the same setting, in which 8851 QuantiFERON-negative schoolchildren aged 6–13 years were randomized to receive a weekly oral dose of placebo or 14,000 IU vitamin D<sub>3</sub> for 3 years [98]. Vitamin D deficiency was very common among study participants at baseline, and the intervention was highly effective in elevating serum 25(OH)D concentrations of participants randomized to the intervention arm. However, no inter-arm differences in risk of QuantiFERON conversion were seen. Another phase 3 RCT investigating effects of weekly vitamin D supplements on risk of QuantiFERON conversion in Cape Town schoolchildren (“ViDiKids,” clinicaltrials.gov identifier NCT02880982) [99] has recently completed and has also yielded null results.

## 6. Studies with active TB disease as end point

### 6.1 Observational studies

In 1985, Davies observed that people migrating to the United Kingdom from countries with a high incidence of LTBI experienced rates of active TB that exceeded rates in their countries of origin and that this increased risk coincided with the development of vitamin D deficiency, probably arising as a result of decreased sun exposure [100]. He suggested that vitamin D deficiency may predispose to reactivation of LTBI, a hypothesis supported by other ecological studies reporting a spring/summer peak in TB notification rates in a wide range of settings, following shortly after the seasonal nadir in population vitamin D status [101,102]. Another ecological study has shown that regional solar radiation is inversely correlated with incidence and severity of tuberculosis in this setting [103], while a cross-sectional investigation conducted in an ethnically diverse group of 462 TB patients in the United Kingdom has reported an

independent association between vitamin D deficiency and risk of extra-pulmonary tuberculosis [104]. This finding raises the possibility that vitamin D deficiency may be implicated in the pathogenesis of extra-pulmonary dissemination, as well as contributing to susceptibility to disease per se.

Further evidence comes from case–control studies investigating whether vitamin D deficiency associates with susceptibility to active TB. More than 50 such primary studies have been conducted to date, with data from them contributing to four meta-analyses [105–108], all of which report statistically significant associations between lower vitamin D status and increased risk of active TB. Potential explanations for an association between vitamin D deficiency and active TB include both causality (i.e., vitamin D deficiency impairs host immune response to MTB and causes susceptibility and extra-pulmonary dissemination), confounding and reverse causality (i.e., active TB causes vitamin D deficiency, due to anorexia, decreased exposure to sunlight in debilitated patients, or MTB-induced dysregulation of vitamin D metabolism [109]).

One approach to eliminate the potential influence of reverse causality using a case–control study design is to investigate whether genetic variation in pathways of vitamin D metabolism, transport, or signaling associates with altered susceptibility to active TB. To date, this line of enquiry has primarily focused on polymorphisms in the VDR. Human VDR is encoded by the *VDR* gene located on chromosome 12q. This gene is polymorphic, and numerous single-nucleotide polymorphisms have been described. The hypothesis that *VDR* variants might associate with susceptibility to active TB was first investigated by Bellamy and colleagues, who reported an association between carriage of the *T* allele of the *TaqI* *VDR* polymorphism and susceptibility to active TB in a case–control study conducted in Gambian adults [110]. Wilkinson and colleagues subsequently reported that associations between susceptibility to TB and carriage of the *T* allele of the *TaqI* *VDR* polymorphism and the *ff* genotype of the *FokI* *VDR* polymorphism in Gujarati Asians living in London were restricted to vitamin D–deficient individuals [111]; this study is the first to report that gene: environment interactions may operate to influence susceptibility to active TB. More than 50 case–control studies investigating the association between *VDR* variants and susceptibility to active TB have now been published. Meta-analyses of these studies report a consistent statistically significant association between the *ff* genotype of the *FokI* polymorphism and susceptibility to active TB in study populations overall (pooled odds ratios ranging from 1.23 to 1.60) [112–115]. Consistent associations for the *TaqI*, *ApaI*, and *BsmI* polymorphisms have not been found overall, although subgroup analysis has revealed an association (odds ratio 1.43)

between the *tt* genotype of the *TaqI* polymorphism and susceptibility to TB in Asian populations [116].

The mechanisms by which *VDR* polymorphisms influence susceptibility to TB are incompletely understood. *FokI* is a nonsynonymous SNP in the translation start site of exon 2 of the *VDR* gene. The SNP is characterized by a C-to-T substitution in a 5' ATG start codon, resulting in a *VDR* protein, which is of 427 amino acids, instead of 424 amino acids, in length [117]. Human monocytes and dendritic cells homozygous for the *F* allele exhibit higher expression of interleukin-12 (IL-12) messenger RNA (mRNA) and protein, and lymphocytes of individuals with the *FF* genotype proliferate more strongly in response to phytohemagglutinin than those of individuals with the *ff* genotype [118]. In contrast to *FokI*, *TaqI* and *BsmI* are synonymous SNPs located in intron 8 and exon 9 of the *VDR* gene, respectively; they are in linkage disequilibrium with each other and with a poly(A) length polymorphism in the 3' untranslated region of the *VDR* gene [119]. Carriage of the *t* allele of the *TaqI* polymorphism has been reported to associate with an increase in *VDR* gene expression. Because the 3'-UTR is a major regulator of mRNA half-life [120], this association was originally thought to be mediated via an effect on mRNA stability [121]; however, subsequent studies have refuted this hypothesis [122,123], and the mechanism for the association is not currently understood.

Further case-control studies have investigated associations between polymorphisms in *Gc* (the gene encoding DBP) and susceptibility to active TB. DBP is a highly expressed multifunctional 58 kDa serum glycoprotein encoded on chromosome 4. Two common polymorphisms at codons 416 and 420 of exon 11 of the *Gc* gene give rise to the three major electrophoretic variants of DBP, termed group-specific component 1 fast (Gc1F), Gc1 slow (Gc1S), and Gc2. These variants differ in their functional characteristics: the Gc1F and Gc1S variants have been reported to have greater affinity for 25(OH)D than the Gc2 variant [124], potentially leading to more efficient delivery of 25(OH)D to the target tissues, while the Gc2 variant is associated with decreased circulating concentrations of 25(OH)D, 1,25(OH)<sub>2</sub>D, and DBP [125,126]. A case-control study conducted in Taiwan has reported an association between the Gc1F allele and susceptibility to TB [127], although studies conducted in India, Russia, Kuwait, and Pakistan did not find any such association [128–131]. A fifth study reported an association between the Gc2 allele of vitamin D-binding protein and susceptibility to active TB among Gujarati Asians living in London. This association was preserved if serum 25(OH)D concentration was < 20 nmol/L, but not if serum 25(OH)D was ≥ 20 nmol/L, suggesting that profound vitamin D deficiency and Gc2 genotype may interact to increase susceptibility to TB [132].

In contrast to the numbers of published cross-sectional and case-control studies, relatively few cohort studies investigating associations between vitamin D status and risk of incident active TB have been conducted. A recent meta-analysis of individual participant data from these studies reported a dose-dependent association between low baseline vitamin D status at baseline and increased risk of incident TB disease subsequently, with risk of TB disease being highest among HIV-positive individuals and in those with severe vitamin D deficiency at baseline [133]. A consistent association was reported by the only other longitudinal study of this kind that has reported since this meta-analysis was conducted [134]. However, confounding cannot be ruled out as an explanation for associations reported in observational studies, and RCTs are needed to establish causality.

## 6.2 Intervention studies

Three phase 3 RCTs investigating potential effects of vitamin D supplementation on risk of incident active TB have reported to date. In the TOV-4 trial, Sudfeld and colleagues randomized 4000 HIV-infected adults in Tanzania with baseline serum 25(OH)D concentrations of less than 75 nmol/L to receive either four weekly oral bolus doses of 50,000 IU vitamin D<sub>3</sub> over 1 month, followed by a daily dose of 2000 IU vitamin D<sub>3</sub> for 11 months, vs. a matching weekly and daily placebo regimen. No difference in risk of incident active TB was seen between arms (hazard ratio 0.78, 95% CI 0.54–1.13). In another trial [98], Ganmaa and colleagues randomized 8851 schoolchildren in Mongolia to receive a weekly oral dose of 14,000 IU vitamin D<sub>3</sub> vs. placebo for 3 years. Again, no effect of the intervention on risk of incident active TB was seen (adjusted risk ratio 0.87, 95% CI 0.49–1.55). Most recently, the ViDiKids trial, conducted in South African schoolchildren, reported no effect of a weekly oral dose of 10,000 IU vitamin D<sub>3</sub> vs. placebo on risk of active TB, although the number of incident cases was small [99].

## 7. Studies of treatment outcome

### 7.1 Observational studies

A handful of observational studies have investigated the relationship between baseline vitamin D status and outcome of anti-tuberculous therapy in patients with active TB. Three cohort studies have reported independent associations between lower vitamin D status and impaired clearance of MTB from the sputum of patients with pulmonary TB during intensive-phase treatment—two in drug-sensitive disease [135,136] and one in

multidrug-resistant (MDR) disease [137]. Additionally, a cohort study conducted in Tanzania has also reported an independent association between vitamin D insufficiency ( $25[\text{OH}]\text{D} < 75 \text{ nmol/L}$ ) and risk of relapse of active tuberculosis in a cohort of 677 patients completing treatment for active TB, 344 of whom had HIV infection [138].

Studies investigating the influence of genetic variation in the vitamin D pathway on treatment outcome are all restricted to the intensive phase of therapy: Roth and colleagues have reported that the *FF* genotype of the *FokI* *VDR* polymorphism and the *Tt* genotype of the *TaqI* *VDR* polymorphism associate with faster sputum culture conversion in a cohort of pulmonary TB patients in Peru [139], while Babb and colleagues reported no difference in time to sputum culture conversion according to *TaqI* or *FokI* *VDR* genotype among South African TB patients [140]. However, Junaid and colleagues did not find any association between sputum smear conversion and polymorphisms in *VDR*, *CYP2R1*, or *DBP* [136].

## 7.2 Intervention studies

In contrast to trials for the prevention of incident active tuberculosis, intervention studies to determine whether adjunctive vitamin D enhances response to antimicrobial therapy can be powered to detect clinically significant effects of treatment with more modest numbers of participants and shorter follow-up. Twenty-one such studies have been published to date, contributing data to six meta-analyses [141–146], all of which have shown no overall effect of adjunctive vitamin D on time to sputum culture conversion. Subgroup analyses in two meta-analyses [144,145] have, however, suggested a possible benefit among patients with MDR TB, which should be investigated in new primary RCTs conducted exclusively in patients with MDR TB.

## 8. Conclusions

A very large body of evidence relating to potential effects of vitamin D in human tuberculosis now exists. Findings from laboratory work have tended to suggest a positive influence of vitamin D metabolites on host response to MTB in cell culture, and observational epidemiological studies have reported associations between higher vitamin D status and favorable clinical outcomes, including lower risk of MTB infection and disease, and better response to antimicrobial therapy in patients with pulmonary disease. By contrast, RCTs of vitamin D for prevention of MTB infection and disease, and for treatment of pulmonary TB, have tended

to yield null results—with the possible exception of patients being treated for MDR TB, where subgroup analyses in some meta-analyses have suggested potential benefit. How can this “disconnect” between findings clinical trials vs. laboratory studies and observational epidemiology be explained?

Broadly, there are two possibilities. It may be that positive results from laboratory studies do not reflect physiological conditions, and positive associations from observational epidemiology are non-causal. Alternatively, RCTs may have yielded false-negative results due to problems with their design or execution.

With regard to laboratory studies, lack of relevance to in vivo responses may reflect investigation of concentrations of  $1,25(\text{OH})_2\text{D}$  that are several orders of magnitude higher than those measured in the circulation or in extracellular fluid in humans [40]. Moreover, cell culture systems may not contain plasma proteins such as DBP or albumin, which may affect bioavailability of vitamin D metabolites in vivo [147]. Additionally, many cell culture systems investigate effects of vitamin D metabolites in a single cell type (most commonly mononuclear phagocytes) [31,42]. This reductionist approach ignores potential effects of vitamin D on the function of other cellular players, including T cells, which may antagonize or regulate effects of vitamin D on macrophage function [40].

With regard to epidemiological studies, non-casual associations may arise via two main mechanisms. First, confounding may be operating, whereby “third factors” related to both exposures and outcomes of interest are either imperfectly measured (residual confounding) or not controlled for at all (unmeasured confounding) in multivariable analyses testing for associations [148]. Alternatively, or additionally, reverse causality may operate, such that outcomes may actually influence the exposures: for example, active TB disease might reduce circulating  $25(\text{OH})\text{D}$  concentrations, either by metabolizing cholecalciferol itself [149] or by dysregulating host vitamin D metabolism [150]—a possibility that has also been raised in other inflammatory pulmonary diseases [151].

With regard to clinical trials, false-negative results may arise as a consequence of factors including participant characteristics (e.g., where baseline vitamin D status is adequate prior to supplementation [152]), use of inappropriate dosing regimens (e.g., if vitamin D is administered at too low a dose to produce sustained elevations in circulating  $25[\text{OH}]\text{D}$  concentrations [153]), masking of vitamin D effects by more effective antimicrobial therapy [154,155], poor adherence to study supplements, high rates of loss to follow-up, or other issues constraining statistical power.

Given the challenges in interpreting results of the aforementioned studies, it may be that Mendelian

randomization studies [156] can yield additional insights into a potential role for vitamin D deficiency in influencing susceptibility to, or severity of, tuberculosis—as they have done for multiple sclerosis [157]. Ultimately, however, consistent null results from RCTs of vitamin D for prevention and treatment of TB hold greater weight with clinical and public health policy-makers than positive results from laboratory and observational studies. Accordingly, international guidelines for the management and control of TB do not specify a role for vitamin D either in the prevention or in the treatment of this disease [158].

## 9. Summary points

- Cod liver oil and vitamin D<sub>2</sub> were used to treat tuberculosis in the pre-antibiotic era, with reported success.
- Laboratory studies have elucidated diverse mechanisms by which vitamin D metabolites support innate anti-mycobacterial immune responses.
- Observational epidemiological studies have reported consistent associations between low vitamin D status and increased risk of tuberculosis infection and disease.
- Randomized controlled trials of vitamin D for prevention and treatment of tuberculosis have yielded consistent null results. Consequently, international guidelines do not currently recommend a role for vitamin D supplements in either prevention or treatment of tuberculosis.

# The role of vitamin D in COVID-19

*Sebastian T. Lugg and David R. Thickett*

Institute of Inflammation and Ageing, College of Medical and Dental Sciences, University of Birmingham, Birmingham, United Kingdom

## OBJECTIVES

- Present an introduction to COVID-19 and vitamin D.
- Discuss the potential biological mechanisms of vitamin D and COVID-19 infection.
- Review of the results of key observational studies of vitamin D status and COVID-19.
- Present the results of studies and clinical trials of vitamin D supplementation and COVID-19.
- Discussion on current guidance and the areas for future research.

## 1. Introduction

COVID-19 is caused by the novel coronavirus (SARS-CoV-2), thought to originate from a food market in Wuhan, China, in mid-December 2019. COVID-19 has since spread globally, and on March 11, 2020, it was named a pandemic by the WHO, and as of April 3, 2022, there have been an estimated 489 million positive cases and 6 million deaths globally [1]. COVID-19 symptoms include dry cough, fever, breathlessness, sore throat, nasal congestion, loss of smell, and malaise. The severity of COVID-19 infection ranges from asymptomatic, mildly symptomatic, moderate disease requiring hospitalization, and severe and critical requiring need for admission to the intensive care unit (ICU). Multiple risk factors for worse outcomes in COVID-19 include older age, black and minority ethnic groups, obesity, cardiovascular comorbidity, and

malignancy, which are also risk factors for vitamin D deficiency [2]. Therefore, there has been great interest in the role of vitamin D in COVID-19 infection and severity. Since the beginning of the pandemic, there have been an increasing number of genetic variants, which have given an evolutionary advantage of the virus to infect and spread through populations; however, there is a lack of information about the role of vitamin D in the severity of different variants of SARS-CoV-2.

SARS-CoV-2 is an enveloped virus with a positive-sense single-stranded ribonucleic acid (RNA) genome. SARS-CoV-2 contains four structural proteins: spike (S), membrane (M), envelope (E), and nucleocapsid (N). The SARS-CoV-2 virus enters the cell via the spike protein, which has a key role in receptor recognition and cell membrane fusion. The spike protein is comprised of two subunits (S1 and S2). The S1 subunit binds to the enzyme angiotensin-converting enzyme 2 (ACE2) [3], which is present in upper airway epithelial cells in high concentrations [4].

The major causes of morbidity and mortality of SARS-CoV-2 infection are through the development of acute respiratory distress syndrome (ARDS). The initial infection of the respiratory virus results in a phase of viral replication. This is followed by a recruitment of inflammatory cells including neutrophils and monocytes/macrophages from proinflammatory cytokines from viral-infected cells. Resultant cellular apoptosis of lung epithelial cells and endothelial cells causes vascular leakage and alveolar oedema, developing into ARDS.

## 2. Vitamin D and immunity and inflammation: relevance to COVID-19 infection

The vitamin D receptor (VDR) is present in most tissues including immune cells. Vitamin D when bound

to the VDR can regulate many target genes with effects on immunomodulation of the immune system and lung cell function. Vitamin D has a role in both the innate and adaptive immune system. The proposed mechanisms by which vitamin D can protect/limit the severity of COVID-19 infection are summarized in Fig. 99.1.

The first potential mechanism by which vitamin D can influence the course of COVID-19 infection is via its well-established effects on the immune system. In the innate immune system, the active form of vitamin D, 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ), has a role in antimicrobial activity and limiting inflammation/promoting tissue repair. Antigen-presenting cells (APCs) such as activated macrophages and dendritic cells (DCs) express cytochrome P450 family 27 subfamily B member 1,  $1\alpha$ -hydroxylase (CYP27B1), which converts precursor 25-hydroxyvitamin D ( $25(\text{OH})\text{D}$ ) into  $1,25(\text{OH})_2\text{D}$  [5,6] (see Chapter 9).  $1,25(\text{OH})_2\text{D}$  reduces production and release of proinflammatory cytokines by blocking transcription factor nuclear factor kappa B (NF- $\kappa$ B) translocation to the nucleus [7]. Vitamin D also has a role in monocyte to macrophage differentiation and triggers autophagy needed to defend against viral infection [8].  $1,25(\text{OH})_2\text{D}$  also has a role in microbial killing by activation of Toll-like receptors (TLRs) (see Chapters 94 and 95).  $1,25(\text{OH})_2\text{D}$  induces CD14 [9], which is a TLR coreceptor; subsequent TLR activation leads to induction of reactive oxygen species (ROS) and antimicrobial peptides. The potential of ROS damage is limited by  $1,25(\text{OH})_2\text{D}$  through induction of antioxidants such as glutathione synthase [10].  $1,25(\text{OH})_2\text{D}$  indirectly induces defensin Beta-2 [11], which stimulates antiviral cytokines and chemokines involved in cellular recruitment of innate immune cells.  $1,25(\text{OH})_2\text{D}$  also induces expression of cathelicidin antimicrobial peptide (CAMP or LL-37) in epithelial cells and myeloid cells to promote antibacterial and antiviral immunomodulation and tissue repair [12,13]. In patients with non-COVID-19 sepsis, a single dose of 400,000 IU of vitamin D<sub>3</sub> treatment resulted in an increase in serum cathelicidin [14]. With regard to COVID-19, LL-37 competitively binds to SARS-CoV-2, which inhibits the virus binding to ACE2 and subsequent invasion into the cell [15] (see Chapter 95).

In the adaptive immune system,  $1,25(\text{OH})_2\text{D}$  has an overall inhibitory role by decreasing the maturation of DCs via reduced expression of costimulatory cell surface markers [16] and by decreasing DC antigen expression and subsequent activation of T cells to mount an adaptive response.  $1,25(\text{OH})_2\text{D}$  also inhibits the development of T helper type 1 (Th1) cells, thereby inhibiting the production of interleukin-2 (IL-2) and interferon  $\gamma$  (INF $\gamma$ ), and also suppresses Th17 cells, which produce the inflammatory cytokine IL-17 [17]. In suppressing Th1 cells,  $1,25(\text{OH})_2\text{D}$  promotes the transition of proinflammatory

Th1 cells to suppressive T helper type 2 (Th2) phenotype producing IL-10 [18]; the effects of  $1,25(\text{OH})_2\text{D}$  can occur in the absence of the APC such as DC [19]. Exposure of DCs to  $1,25(\text{OH})_2\text{D}$  results in increased expression of regulatory transcription factor forkhead box P3 (Fox3) [17], and induction of regulatory T cells (Treg), which have an important role in immune tolerance (see Chapter 96). Thus, vitamin D has a role in the shift from a Th1 to Th2 environment, as there is prevention of further recruitment of T lymphocytes and proliferation, and suppression of IL-12 resulting in more Th2, which produces IL-4 (differentiation of Th0 to Th2), IL-5, and IL13. In addition, induction of Treg cells has an important role in preventing/limiting the cytokine/chemokine release associated with ARDS caused by SARS-CoV-2 and other viruses. The role of vitamin in the adaptive immune system has been investigated in patients with COVID-19. This has been shown in a study, which showed that serum  $25(\text{OH})\text{D}$  levels  $\leq 11.4$  ng/mL (vitamin D deficiency) were associated with increased circulating Th2 and decreased Th17 in patients with COVID-19 [20]. Furthermore, in patients with COVID-19, CD4 T cells from bronchoalveolar lavage from the lungs showed a higher proportion of Th1 cells than uninfected controls, and these cells were characterized by derepression of genes that are normally downregulated by vitamin D [18]. Furthermore, Th1 cells from COVID-19 patients were able to convert  $25(\text{OH})\text{D}$  to  $1,25(\text{OH})_2\text{D}$  and are thus not solely reliant on paracrine effect of  $1,25(\text{OH})_2\text{D}$  produced by macrophages or DCs (see Chapter 9). Thus, the antiinflammatory processes of the adaptive immunity in COVID-19, and other inflammatory diseases, are likely to be compromised in the setting of vitamin D deficiency.

The second potential mechanism associated with COVID-19 mortality that may be impacted by vitamin D is the renin-angiotensin system (RAS). Angiotensin-converting enzyme 2 (ACE2) plays a role in cleaving angiotensin II, thus limiting the RAS. Vitamin D has been shown to increase ACE2 levels, therefore inhibiting RAS [21]. Signal transduction in the RAS is modulated by two pathways, the classical angiotensin II type I receptor (AT1R) axis and the alternative mass receptor (MasR) axis. Vitamin D inhibits the classical pathway while enhancing the alternative pathway [22], promoting antiinflammatory, antioxidative, and antiapoptosis, therefore reducing the effect of angiotensin in inflammation and fibrosis, vasoconstriction, and thrombogenicity. The binding of SARS-CoV-2 to ACE2 subsequently reduces ACE2 levels. Absence of ACE2 in mice results in severe lung injury [23], and RAS has been implicated in the development of ARDS. Polymorphisms of the ACE gene have also been shown to be linked to ARDS, providing further evidence of a role for the RAS in the development of ARDS [24,25].

The final potential target for vitamin D in COVID-19 relates to the lung epithelial permeability is associated with ARDS. Similar to its effects on other barrier tissues such as the gastrointestinal tract (see Chapter 97), Vitamin D plays a key role in maintaining the integrity of tight junctions (TJ) and adherens junctions (AJ) within the pulmonary epithelial barrier. TJ and AJs are significantly impaired in *Vdr* knockout mice [26], which is associated with increased alveolar permeability and more severe lung injury following exposure of lipopolysaccharide, which is present on the cell surface of gram-negative bacteria [27]. Airway epithelial cells express CYP27B1, where  $1,25(\text{OH})_2\text{D}$  has a role in proliferation and reducing apoptosis following inflammation, thus promoting epithelial integrity [26].

### 3. Vitamin D and respiratory tract infections

Vitamin D has previously been shown to reduce the risk of respiratory infections. In a metaanalysis of randomized controlled trials (RCTs) including 10,933 participants, supplementation reduced the risk of one or more acute respiratory tract infections (ARIs) from 42.2% to 40.3% [28]. The benefit was most observed in those who were deficient at baseline (55%–40.5%). An updated version of this metaanalysis included 43 RCTs [29], which concluded that vitamin D was safe and reduced ARI, although the reduction in ARI was modest (odds ratio [OR] of 0.92; 95% CI 0.86–0.99) in 37 studies of 23,364 participants assessed. Furthermore, this benefit was not seen with intermittent dosing, and protection was found in those who were supplemented on 400–1000 international units (IU)/day for 12 months and aged between 1 and 16 years [29].

Further support of a role for vitamin in preventing viral respiratory tract infections has been shown in a study where children supplemented with vitamin D<sub>3</sub> during the winter are less likely to develop influenza A [30]. There is also an association between vitamin D genetics and the severity of respiratory infection. VDR polymorphisms (FokI) resulting in lower transcriptional activity of VDR have been shown to be associated with

severe respiratory syncytial virus (RSV) in infants [31]. Furthermore, in infants with bronchiolitis, severe vitamin D deficiency (serum  $25(\text{OH})\text{D} < 20 \text{ ng/mL}$ ) was associated with higher admission to ICU and longer length of hospital stay [32].

### 4. Vitamin D and COVID-19: geographical latitude and UV radiation

Early in the pandemic, population-based epidemiological studies demonstrated a link between SARS-CoV-2 and geographical latitude. COVID-19 infection cases are fewer and less severe in countries closer to the equator [33], and the mortality of COVID-19 infection increased with northerly latitude after adjustment for age [34]. This is likely due to sun exposure, the natural source of vitamin D (see Chapter 3), suggesting a link between latitude, vitamin D, and COVID-19 risk [35]. For most parts of the globe, this also implies seasonality with regard to vitamin D and COVID-19 [36], as is the case for other respiratory viruses such as influenza and swine flu (H1N1) [37].

Ultraviolet-B (UVB) radiation has also been shown to be associated with reduced COVID-19 mortality [38]. A study from UK Biobank cohort found that ambient UVB measured over the preceding 135 days was inversely associated with hospitalization and death, though it was not associated with COVID-19 infection risk [39]. The mortality rate ratio (MMR) of COVID-19 has been shown to be 32% (95% CI 48%–12%) per  $100 \text{ kJm}^{-2}$  increase in daily mean ultraviolet-A (UVA) across three studies in the United States, England, and Italy [40]. This finding was thought to possibly be mediated via cutaneous nitric oxide release. A further study from the United States, using the Nurse's Health Study II cohort, included 39,315 participants and 1768 testing positive for SARS-CoV-2 infection, with predicted  $25(\text{OH})\text{D}$  levels based on questionnaire data from 2015 [41]. The study found higher predicted circulating  $25(\text{OH})\text{D}$  levels were associated with reduced risk of SARS-CoV-2 infection and hospitalization. In addition, there was an association between UVA and UVB exposure and SARS-CoV-2 infection.

**FIGURE 99.1** Proposed mechanisms of the protective effect of  $1,25(\text{OH})_2\text{D}$  against sars-cov-2 infection. (1)  $1,25(\text{OH})_2\text{D}$  maintains the integrity of tight junctions and adherens junctions within the pulmonary epithelial barrier and reducing alveolar permeability in response to sars-cov-2 infection. (2) conversion of  $25(\text{OH})\text{D}$  to  $1,25(\text{OH})_2\text{D}$  in the innate immune system promotes antimicrobial activity of alveolar macrophages and limits inflammation/promotes tissue repair. (3)  $1,25(\text{OH})_2\text{D}$  in the adaptive immune system inhibits antigen presentation by dendritic cells and reduces T helper 1 (Th1) cells and promotes Th2 cells and T regulatory cells (treg), thus reducing proinflammatory cytokine release associated with COVID-19 infection. (4)  $1,25(\text{OH})_2\text{D}$  is involved in the renin–angiotensin system (RAS) by cleaving angiotensin II (ang II) and increasing angiotensin II enzyme, promoting systemic antiinflammatory, antifibrotic, and antioxidant pathways, and reducing vasoconstriction and thrombogenesis.

## 5. Vitamin D and COVID-19: community observational studies

There have been many observational studies that have assessed association between vitamin D and COVID-19 infection, severity, and mortality. The characteristics of selected studies investigating vitamin D deficiency and COVID-19 are shown in Table 99.1. Earlier observational studies during the pandemic used historic vitamin D results to investigate this link. A study investigating the mean 25(OH)D levels and the cases/deaths of COVID in 2020 found there was a negative correlation between mean 25(OH)D levels and infection rate and mortality [42]. Another population-based study in the United States in 2020 including 191,779 participants demonstrated that SARS-CoV-2 positivity rates were inversely correlated to circulating 25(OH)D levels from the preceding 12 months [43]. A UK Biobank study of 348,958 participants, including 449 patients with COVID-19 infection and historic 25(OH)D levels between 2006–10, found no increase in 25(OH)D levels in multivariate analysis [44]. A follow-up study of this data including in 341,484 participants found, again, no association with COVID-19 infection and mortality after adjustment for multiple variables including body mass index (BMI) and ethnicity [45]. However, the biobank studies are severely limited in drawing conclusions due to the use of serum 25(OH)D levels obtained up to 10 years prior to COVID analysis.

A single-center retrospective cohort study from the United States in 2020 looked at COVID-19 infection and vitamin D status within the previous year ( $<20$  ng/mL) including 489 participants [46]. Those with likely vitamin D deficiency ( $<20$  ng/mL) had an associated increased COVID-19 risk on multivariate analysis compared with those who were likely sufficient (1.77; 95% CI 1.12–2.81;  $P = .02$ ). A retrospective study in Israel in 2020, which included 7807 people who had tested for COVID-19 and had previous 25(OH)D levels performed (not specified when), found that low plasma 25(OH)D ( $<30$  ng/mL) was an independent risk factor for COVID-19 infection (OR 1.45; 95% CI 1.08–1.95,  $P < .001$ ) and hospitalization (OR 1.95; 95% CI 0.98–4.845,  $P = .061$ ) [47]. Another retrospective study of 2020 veterans in the United States, 2020 veterans included patients with positive SARS-CoV-2 and blood test within 15–90 days also found inverse relationship with mortality and severity of COVID-19 infection [48].

There have been a number of studies, which have looked at the association of ethnicity, vitamin D deficiency, and COVID-19. One of which used propensity score methods to examine the effect of ethnicity on the relationship between vitamin D status and COVID-19 test positivity using electronic health data

from unmatched ( $n = 21,629$ ) and matched ( $n = 16,602$ ) with testing of 25(OH)D levels [49]. The study found deficiency ( $<30$  ng/mL) was not associated with COVID-19 positivity overall, though when analyzed as a continuum, 25(OH)D levels  $<10$  ng/mL lowered odds of testing for COVID-19 in those of white (OR 0.935;  $P = .003$ ) and not black ethnicity (OR 0.994;  $P = .75$ ). In contrast to these findings, another study investigated COVID-19 infection in 13,000 participants of the US Black Women's Health Study who provided blood samples between 2013– and 2017; these were subsequently analyzed for 25(OH)D in addition to online questionnaire [50]. In 5081 eligible participants, the study found that black women with lower 25(OH)D levels were at increased risk of COVID-19 infection on multivariate analysis (20–29 ng/mL; OR 1.48; 95% CI 0.95–2.30;  $<20$  ng/mL; OR 1.69; 95% CI 1.04–2.72). Another study looking at UK healthcare workers who self-isolated with symptoms during the first wave of the pandemic [51] half of who had seroconverted found that seroconversion was increased in those who were vitamin D deficient compared with non-vitamin D-deficient staff (72% vs. 51%). Black, Asian, or minority ethnicity (BAME) or vitamin D deficiency ( $<30$  nmol/L) were independent factors of being positive for SARS-CoV-2 antibodies (indicating previous COVID-19 infection). Thus, ethnicity appears to have a role in risk of developing COVID-19, where vitamin D deficiency is more common, though vitamin D deficiency was an independent risk factor for seropositivity (OR 2.6; CI 1.41–4.8;  $P = .002$ ).

For patients who are hospitalized for COVID-19, there are several treatments that can be used, which have been shown to improve outcomes. The main treatment involves either antiviral therapy or antiinflammatory treatment. Remdesivir was the first antiviral to be approved for treatment, with mechanism of an RNA-dependent RNA polymerase inhibitor, which has an inhibitory effect of SARS-CoV-2 and has been shown to shorten recovery time in patients hospitalized with COVID-19 [59]. Dexamethasone has an antiinflammatory role, and in those hospitalized for COVID-19, has been shown to reduced mortality in those requiring oxygen therapy [60] and now is widely used in clinical practice. There have since been monoclonal antibody therapies used in patients with COVID-19, which have antiinflammatory effects. Anti-IL6 therapies, such as tocilizumab, have been shown to improve survival in patients with hypoxia and systemic inflammation [61]. Further therapies such as baricitinib has a role in patients hospitalized with COVID-19 requiring supplemental oxygen and suppresses the JAK-STAT pathway, preventing proinflammatory cytokine release and systemic inflammation, and has been shown to reduce 28-day mortality in hospitalized patients [62]. Sotrovimab,

a neutralising monoclonal antibody, directed against the spike protein, with a role for treatment to nonhospitalized high-risk patients with mild to moderate COVID-19 [63]. Vitamin D also shares similar mechanisms with regard to antiviral (prevention) and antiinflammatory effects (treatment) of COVID-19 and therefore could be considered as a concomitant treatment in prevention and/or treatment.

## 6. Vitamin D and COVID-19: hospital observational studies

For those who are hospitalized due to COVID-19 infection, studies have investigated the role of vitamin D in relation to infection and severity of disease. An Israeli retrospective study in 2020 included 41,757 individuals who tested positive for COVID-19 matched against 417,570 non-COVID-19 controls; another 2533 who were hospitalized with COVID-19 were matched against 2533 patients who tested positive but were not hospitalized [52]. The study found an inverse correlation between 25(OH)D levels and developing COVID-19 infection and being hospitalized with infection. Those with lowest levels ( $<30$  nmol/L) had highest risk of infection (OR 1.246; 95% CI 1.21–1.30) and severe disease (OR 1.513; 95% CI 1.22–1.86). A retrospective case–controlled Spanish study included 216 hospitalized patients with COVID-19, and 197 population controls found that 25(OH)D levels were lower in COVID-19 cases (82.2% versus 47.2%) [53]. Furthermore, 25(OH)D inversely correlated with acute phase inflammatory markers (ferritin) and D-dimer (associated with coagulopathy). This study, however, did not find significant differences between vitamin D deficiency and severity of COVID-19 infection. In contrast, a prospective study in Germany assessed 25(OH)D levels at presentation for COVID-19 in 185 patients. There was an association between vitamin D deficiency (defined as  $<12$  ng/mL ( $<30$  nmol/L) serum 25(OH)D) and COVID-19 severity (requiring invasive mechanical ventilation) and mortality [54].

Those patients with severe COVID-19 with ARDS require admission to ICU for ventilatory support; a retrospective observational study in patients with COVID-19 in ICU found 81% of patients were vitamin D deficient ( $<10$  ng/mL ( $<25$  nmol/L) serum 25(OH)D), and these patients had 50% mortality risk compared with those with 25(OH)D levels  $\geq 10$  ng/mL (5% mortality risk) [55]. This suggested that vitamin D deficiency is associated with poorer prognosis in these individuals. A further study of COVID-19 patients aged 30–60 years ( $n = 154$ ) found that vitamin D

deficiency was higher in those with severe disease (requiring ICU) compared with asymptomatic cases (96.82 vs. 32.69%) [56]. Vitamin D–deficient patients had increased levels of acute phase inflammatory markers (IL-6, ferritin, and tumor necrosis factor  $\alpha$  [TNF $\alpha$ ]) and increased mortality.

A UK cross-sectional study measured plasma for 25(OH)D concentrations from 295 patients hospitalized with COVID-19, 93 patients with influenza A, and 139 survivors from nonselected critical illness prior to the pandemic [57]. The study found that vitamin D deficiency was observed in the majority of hospitalized cases of COVID-19 or influenza A, and that vitamin D deficiency correlated with disease severity, and persisted in those of non-COVID-19 critical illness survivors. There therefore may not be a causal role for vitamin D deficiency in COVID-19 severity, as serum levels of 25(OH)D have been reported to be a negative acute phase reactant [64,65]. Therefore, lower serum levels of 25(OH)D might occur as a consequence of more severe systemic disease rather than be a cause of this disease. A reduction in 25(OH)D levels has been seen in other acute illnesses such as acute pancreatitis and following surgery [65]; a possible biological explanation may be due to the fact the majority of 25(OH)D is bound to vitamin D–binding protein (DBP) and serum albumin, which both decrease during acute illness [66].

To investigate further the link between 25(OH)D status and COVID-19 disease severity, a UK study assessed mortality of 472 patients hospitalized for COVID-19 [58]. The authors found a U-shaped association between total 25(OH)D levels and mortality, with levels  $<25$  nmol/L and  $>100$  nmol/L associated with increased mortality (OR 2.37; 95% CI 1.17–4.78 and OR 4.65; 95% CI 1.51–14.34, respectively). The higher risk seen in those with high levels should be approached with caution as the numbers with levels  $>100$  nmol/L were very low ( $n = 18$ ). There were, however, no differences found between either free or bioavailable 25(OH)D and risk of death. Therefore, the relationship between COVID-19 and vitamin D is difficult to be explained by the onset of acute illness alone. There are two recent metaanalyses on this question with divergent conclusions. In identifying 31 observational studies, one systematic review found a trend for an association between low serum 25(OH)D levels and COVID-19-related outcomes, but the relationship was not statistically significant [67]. Another review looked at 17 observation studies finding that vitamin D deficiency was associated with greater severity of COVID-19 [68]. Thus, further research is needed to determine if vitamin D supplementation can reduce the severity of COVID-19.

## 7. Vitamin D and COVID-19: effects of polymorphisms in VDR and vitamin D-binding protein genes

As detailed in other chapters in this book (see Chapters 60 and 61), single-nucleotide polymorphic (SNP) variations in genes encoding key components of the vitamin D system play a crucial role in modulating the vitamin D metabolism, transport, and function. However, while these vitamin D SNPs have been linked to many other human diseases, there have been a few studies that have investigated the impact of vitamin D SNPs on COVID-19. One study found that serum 25(OH)D levels were not related to COVID-19 outcomes, but SNPs in the *VDR* gene were independently associated with COVID-19 severity and survival [69]. A Portuguese study showed that a polymorphism in the *DBP* gene (*GC*), referred to as RS2282679, was associated with severity of COVID-19 infection [70]. *DBP* not only has a role in transporting vitamin D metabolites in the circulation but also has an indirect role as a neutrophil chemotactic factor [71], alveolar macrophage activation, and systemic actin binding, indicating a broader role in the inflammatory process [72] (see Chapter 7). *DBP* is particularly important in relation to 25(OH)D levels in severely ill COVID-19 patients with ARDS; circulating levels of *DBP* have been shown to drop by about a third in ARDS [73]. However, because *DBP* is the main serum binder of 25(OH)D, a drop in *DBP* levels may, indirectly, lead to an increase in free 25(OH)D concentration, which may enhance the availability of 25(OH)D for immune cells, notably APC (see Chapter 7). The relationship between *GC* variants, *DBP* levels, and 25(OH)D function is complex, and SNPs contribute a relatively small proportion of overall vitamin D variability. Thus, the role of *DBP*/vitamin D homeostasis in the setting of COVID-19 is still unclear.

## 8. Vitamin D and SARS-CoV-2 vaccination response

As well as assessing the impact of 25(OH)D status on COVID-19 infection and disease severity, studies have also investigated the effect of vitamin D on immune response following SARS-CoV-2 vaccination. A study looked at 97 healthcare workers following a first dose of vaccine (BNT162b2) included serum 25(OH)D measurements at baseline [74]. The study found that in individuals with 25(OH)D > 50 nmol/L, there was on average a 29.3% greater peak value of antibody response. In contrast, a German study looked at the SARS-CoV-2 IgG antibody and neutralization potency in association with 25(OH)D concentrations in healthy

adults [75]. The study found no association between vitamin D status and vaccination response as measured as SARS-CoV-2 IgG. In addition, vitamin D replacement at a dose of 800 or 3200 IU/day did not influence the protective efficacy or immunogenicity of the SARS-CoV-2 vaccination when given to adults who had suboptimal vitamin D status at baseline [76]. Thus, currently, there is conflicting evidence of the relationship between vitamin D status and SARS-CoV-2 vaccination response. A previous metaanalysis of influenza vaccination and serum 25(OH)D found no difference between vitamin D levels and immunogenic response following vaccination [77]. However, a strain-specific differences may exist, for example, the seroprotection rates of influenza A subtype and B strain in vitamin D-deficient patients were lower than in patients with normal vitamin D levels.

## 9. Vitamin D supplementation and COVID-19

Following observational data on the association of vitamin D deficiency to COVID-19 infection, severity, and mortality, the effects of supplementation have been investigated and summarized in Table 99.2. A Spanish observational study included 15,968 hospitalized COVID-19 patients from the region of Andalusia between January to November 2020 [78], including those who were prescribed vitamin D prior to admission. The study found a relationship between patient survival and vitamin D replacement within 15 days; higher in those who had calcifediol (HR 0.67; 95% CI 0.50–0.91) than cholecalciferol (HR 0.75; 95% CI 0.61–0.91), and stronger association in those who had this within 15 days compared with 30 days prior to hospitalization. A French quasi-experimental study included 66 nursing home residents. The intervention ( $n = 57$ ) of a bolus of vitamin D supplementation of 80,000 IU vitamin D was associated with less severe disease and better survival than the comparator group ( $n = 9$ ) [79].

Several RCTs have assessed the effect of vitamin D supplementation. A Mexican study included 42 outpatients who had asymptomatic or mildly symptomatic COVID-19 infection [80]; 22 were randomized to receive 10,000 IU vitamin D for 14 days, the remaining 20 patients were control. After 7 and 14 days of follow-up, the supplemented patients presented more symptoms of fever compared with those who were not supplemented. The SHADE study from India randomized patients to receive 60,000 IU vitamin D for 7 days in asymptomatic or mildly symptomatic individuals with 25(OH)D levels <20 ng/mL with  $n = 16$  in the intervention and  $n = 24$  in the control [81]. The study found that fibrinogen levels were significantly reduced in the vitamin D-treated group; furthermore, an increased

**TABLE 99.2** Characteristics of selected studies investigating vitamin D supplementation/treatment and COVID-19.

Study, year	Country	Design	Sample and group size	Treatment	Findings
Loucera C et al. [78]	Spain	Retrospective cohort study	15,968	Prescription of vitamin D replacement within 15–30 days of admission	In COVID-19 hospitalized patients, vitamin D replacement was associated with survival, higher in those received therapy in 15 days and in those who had calcifediol than cholecalciferol.
Nogues et al. [92]	Spain	Prospective cohort study	838 total 447 treated 391 not treated	Prescription of calcifediol 532 µg on day 1 plus 266ug on day 3, 7, 15, and 30	Reduced ICU admission in the treated group, including on adjusted logistic regression analysis. Increased mortality in the nontreated group.
Annweiler et al. [79]	France	Quasi-experimental	66 total 57 treated 9 control	800,000 IU oral bolus in the week of diagnosis or in previous month verses untreated control	In nursing home residents, vitamin D treatment was associated with less severe disease and better survival.
Sanchez-Zuno et al. [80]	Mexico	RCT	42 total 22 treated 20 control	10,000 IU/day for 14 days verses untreated control	In outpatients with asymptomatic or mildly symptomatic COVID-19 infection, immunomodulatory effects of vitamin D were linked to COVID-19 symptoms.
Rastogi et al. [81]	India	RCT	40 total 16 treated 24 control	60,000 IU/day of cholecalciferol for 7 days versus placebo control	In asymptomatic/mildly symptomatic COVID-19-positive vitD deficient (<20 ng/mL), treatment reduced fibrinogen levels, and increased proportion became PCR negative.
Lakkireddy et al. [82]	India	RCT	88 total 44 treated 43 control	60,000 IU/day for 8–10 days (depending on BMI) versus untreated control	Vitamin D treatment was associated with reduction in inflammatory makers.
Elamir et al. [83]	United States	RCT	50 total 25 treated 25 control	0.5 µg calcitriol for 14 days or hospital discharge versus untreated control	No difference in LOS, ITU admission, or mortality. Improvement of oxygenation status at discharge in the treatment group.
Murai et al. [84]	Brazil	RCT	240 total 120 treated 120 control	200,000 IU single-dose oral vitamin D (n = 60) or placebo (n = 60)	In hospitalized patients with moderate/severe COVID-19, no difference in clinical outcomes including LOS.

*Continued*

**TABLE 99.2** Characteristics of selected studies investigating vitamin D supplementation/treatment and COVID-19.—cont'd

Study, year	Country	Design	Sample and group size	Treatment	Findings
Cannata-Andia et al. [85]	Spain	RCT	543 total 274 treated 269 control	Oral bolus of cholecalciferol 100,000 IU versus untreated control	In moderate–severe COVID-19, hospital LOS, ITU admission and mortality did not differ between groups. In the cohort analysis, higher serum 25(OH)D at admission (>25 ng/mL) was associated with better outcomes.
Maghbooli et al. [86]	Iran	RCT	106 total 53 treatment 53 control	25 µg calcifediol once/day (3000–6000 IU/day equivalent) for 60 days versus placebo control	In hospitalized patients with vitD deficiency (<30 ng/mL), treatment was associated with increase in lymphocyte percentage and NLR but no difference in LOS and hospitalization, ITU, or mortality.
Entrenas castillo et al. [87]	Spain	Pilot RCT	76 total 50 treatment 26 control	Oral calcifediol 0.532 mg on admission; 0.266 mg on day 3 and 7 and then weekly until ITU admission versus untreated control	Increase admission to ITU in untreated group and no deaths in treated group.
Sabico et al. [88]	Saudi Arabia	RCT	69 total 36 treatment A 33 treatment B	5000 IU/day (A) versus 1000 IU/day (B) for 2 weeks	Increased dose treatment associated shorter time for recovery and return of sense of smell
Joliffe et al. [89]	United Kingdom	RCT	6200 total 1550 treatment A 1550 treatment B, 3100 control	Using test and treat approach for 25(OH)D levels <75 nmol/L; 6 months of either 3200 IU/day (A) or 800 IU/day (B), or no offer or test/treatment	Test and treat approach did not reduce risk of all-cause ARI.

*IU*, international unit; *RCT*, randomized controlled trial; *25(OH)D*, 25-hydroxyvitamin D; *BMI*, body mass index; *PCR*, polymerase chain reaction; *NLR*, neutrophil lymphocyte ratio; *LOS*, length of stay; *ICU*, intensive care unit; *ARI*, acute respiratory infection.

proportion in the treated group became SARS-CoV-2 negative on polymerase chain reaction (PCR) testing.

Another RCT from India investigated supplementation in patients with vitamin D deficiency (25(OH)D < 30 ng/mL) with mild to moderate COVID-19 infection. The patients were given 60,000 IU/day vitamin D for 8–10 days depending on BMI, versus standard treatment controls ( $n = 44$  and  $n = 43$ , respectively, completed the study) [82]. The study found an improvement in inflammatory markers, blood neutrophil:lymphocyte ratio (NLR), C-reactive protein (CRP), lactate dehydrogenase (LDH), IL-6, and ferritin in patients who were treated compared with baseline, and between treated and untreated groups. An RCT from Saudi Arabia included patients with mild to moderate COVID-19 to receive once-daily 5000 IU ( $n = 36$ ) or 1000 IU of vitamin D ( $n = 33$ ) for 2 weeks in patients with suboptimal vitamin D status. Increase in vitamin D dose to 5000 IU/day was associated with shorter time for recovery of cough and sense of smell. An RCT from the United States included 0.5  $\mu$ g of calcitriol (1,25(OH)<sub>2</sub>D) daily for 14 days or hospital discharge. Including 25 patients in both arms, this study found improvement in oxygenation at discharge in the calcitriol-treated patients, but this was a pilot study, and patient numbers were small [83].

An RCT from Brazil included 240 patients hospitalized with moderate to severe COVID-19 who received 200,000 IU single oral dose of vitamin D<sub>3</sub> dissolved in a 10 mL peanut oil solution ( $n = 60$ ) or placebo ( $n = 60$ ); no differences in outcomes observed including no difference in length of stay (LOS) [84] and did not include only deficient/insufficient patients. Also, in this study, patients only received vitamin D treatment after several days in hospital, and the effects were studied for a relatively short time (7–10 days), which may not be enough time to raise the serum 25(OH)D to sufficient levels. An international multicenter RCT named COVI-VIT-D investigated a single oral bolus of 100,000 IU at hospital admission in patients with moderate to severe COVID-19 disease and found no differences in outcomes between groups. It is important to recognize that while large bolus doses of vitamin D can successfully elevate serum levels of 25(OH)D, this may be against the backdrop of superinduction of the vitamin D catabolic system (induction of the enzyme CYP24A1, for example) that may rapidly inactivate any 1,25(OH)<sub>2</sub>D that is generated [28]. In the cohort analysis, higher serum calcifediol levels at admission were associated with better outcomes [85]. An Iranian study included patients with deficiency/insufficiency (<30 ng/mL 25(OH)D) treated with a dose of 25  $\mu$ g (1000 IU)/day oral vitamin D. This treatment increased lymphocyte percentage and neutrophil lymphocyte ratio (NLR) but had no significant effect on LOS and hospitalization,

ICU, or mortality [86], though higher prevalence of patients with diabetes mellitus hypertension and obesity in the vitamin D-treated group. Lower NLR was associated with reduced ICU LOS and mortality. Higher NLR and lower lymphocyte to CRP ratio has been shown in patients with COVID-19 [90].

An open-label RCT from Cordoba in Spain including 76 hospitalized COVID-19 patients investigated the effect of 25-hydroxyvitamin D (calcifediol) treatment 0.532 mg on the day of hospital admission, 0.266 mg on day 3 and 7, and then weekly until ICU admission [87]. Calcifediol does not need to undergo 25 hydroxylation in the liver unlike regular vitamin D (cholecalciferol) and is thus elevated more rapidly in serum [91]. Of the 50 patients on treatment, only 1 was admitted to ICU, while 13 of 26 in the untreated group required admission. There were no deaths in the treated group, while there were two in the untreated group. However, the authors did not state the 25(OH)D levels at baseline. The lack of blinding in the treatment group, the difference in comorbidities between comparison groups and use of antiinflammatory in standard care which would not be considered standard practice limits generalisability of these finding. There are also larger follow-up studies in Spain in which calcifediol was used, including observational cohort studies that found those treated with calcifediol had reduced ICU admission following adjustment on logistic regression [92], and a reduction in in-hospital mortality [93].

A UK-based RCT CORONAVIT NCT04579640 has recently been published [89], which randomized 6200 adults to receive finger prick analysis of serum 25(OH)D, with provision of 6 months of treatment to those with 25(OH)D levels <75 nmol/L (test and treat approach) versus a control group ( $n = 3100$ ) with no offer of testing/treatment but who were allowed to follow the UK governmental guidance of supplementation with 400 IU/day vitamin D. The treatment was open-label and was either higher-dose daily vitamin D replacement (3200 IU/day;  $n = 1550$ ) or lower dosing (800 IU/day;  $n = 1550$ ). The study found no differences in acute respiratory infections and development of COVID-19 between the groups. However, the study to detect COVID-19 was underpowered, as due to effect of public health measures and vaccinations (89.1% had received at least one dose of COVID-19 vaccination by the end of the study), the proportion of those who became infected were only 4.6%, whereas it was initially powered based on predicted 20% in the sample size calculations. In addition, the control group at the end of the study showed a healthy increase in mean 25(OH)D levels of 66.6 nmol/L, and approximately half of the group took vitamin D supplementation during the study period, thus making it more difficult to draw comparisons on the effect of vitamin D replacement in this study.

There have been a number of metaanalyses assessing the role of vitamin D in COVID-19 infection. One meta-analysis [94] included studies up to November 2020 and included 39 studies of which there were 2 RCTs [81,87] and 1 quasi-experimental study [79]. The metaanalysis found that in the vitamin D-deficient patients, there was higher risk of SARS-CoV-2 infection and a higher degree of severity of infection in the 15 studies addressed: even when adjusting for confounders. Another metaanalysis included 17 observational studies and found that in 2756 patients assessed in total, vitamin D deficiency was associated with a higher mortality, ICU admission, and hospital LOS [68]. A systematic review using 13 observational studies found a positive relationship between vitamin D deficiency and risk of COVID-19 in-hospital mortality (OR 2.11; 95% CI 1.03–4.32); pooled data from five studies showed an inverse association between serum vitamin D and risk of in-hospital mortality (OR 0.94; 95% CI 0.89–0.99). Further Cochrane review [95], identified three RCTs [84,85,87], though overall outcome is limited by differences both clinically and methodologically. Further systematic reviews have been published since [96–99]. A further systematic review has found vitamin D supplementation was associated with reduced risk of ICU admission (RR = 0.35; 95% CI 0.20–0.62) and mortality (RR = 0.46; 95% CI 0.3–0.7), whereas no significant impact on the risk of COVID-19 infection [100]. A further metaanalysis found that in observational studies involving nearly 2 million adults, vitamin D deficiency/insufficiency increased susceptibility to COVID-19 and severe disease, although noting a high risk of bias and heterogeneity in studies, and the association of mortality was less robust [101].

## 10. Current guidance of COVID-19 and vitamin D and future research

The serum levels of 25(OH)D required for optimal human health is a topic that continues to be debated and is the focus of two chapters in this book (Chapters 51 and 52). Widely varying target levels for serum 25(OH)D have been recommended by the Endocrine Society [102], Institute of Medicine [103], and the Science Advisory Council for Nutrition (SACN) in the United Kingdom [104]. These levels of 25(OH)D are based on the classical actions of vitamin D and skeletal health, and it is important to recognize that the optimal levels of 25(OH)D and vitamin D supplementation required to achieve this have yet to be determined for extraskeletal actions of vitamin D. Consequently, there is currently no specific guidance on the serum to prevent or treat COVID-19. In the United Kingdom, guidelines encourage people to take vitamin D supplementation to maintain muscle and bone health at a dose of 400 IU

a day for adults [105], and vitamin D is not offered as supplement solely to prevent or treat COVID-19 unless part of a clinical trial. The Endocrine Society's Practice Guidelines for vitamin D replacement is to aim for sufficiency (serum 25(OH)D > 30 ng/mL) [102]. The majority of observational studies had used this as a cutoff to define vitamin D deficiency and found association with levels of 25(OH)D < 30 ng/mL (75 nmol/L) and increased risk of infection and adverse outcomes relative to those with 25(OH)D levels >30 ng/mL. Therefore, preventing/treating vitamin D deficiency based on this target level may have additional benefits against COVID-19.

There is a potential use of vitamin D in two settings. The first is as a nutritional supplement in the community setting to possibly prevent COVID-19 infection and subsequent severity of disease. The other use of cholecalciferol or calcifediol as treatment for patients who already have COVID-19 infection to improve outcome in this setting. Both represent the two sides to vitamin D function with antiviral mechanisms and antiinflammatory mechanisms. Current RCTs alone have not shown definitive benefit of vitamin D treatment in COVID-19 and preventing acute respiratory infection. The studies vary greatly in methodology and are potentially confounded by many of the other public health measures, vaccination response, and treatments during the pandemic. There are further ongoing studies that have yet to report. These include the COVIT-TRIAL with a primary end point of mortality, aiming to recruit 260 patients at/over 65 years of age; those with high-risk COVID-19 (age over 75 or low oxygenation) having no prior vitamin treatment in last month would be randomized to receive  $2 \times 200,000$  IU or 50,000 IU oral drinks [106]. There is also the VIVID Trial, a pragmatic household cluster randomized trial of vitamin D treatment in COVID-19 for 4 weeks of 3200 IU/day, which has a primary outcome of hospitalization and mortality [107]. There is also the VitCov Trial in a Swiss randomized double-blinding placebo controlled multicenter using high-dose vitamin D 140,000 IU [108]. Finally, the CARED-TRIAL in Argentina is planning to treat hospitalized COVID-19 patients with 50,000 IU with at least one risk factor with primary outcome of respiratory Sepsis-related Organ Failure Assessment score (SOFAr) [109].

## 11. Conclusions

In summary, vitamin D deficiency may contribute to SARS-CoV-2 infection through dysregulated innate and adaptive immune response and through upregulated renin-angiotensin system and inflammatory downstream effects. There are multiple ecological

studies showing a link between latitude, UV exposure, 25(OH)D levels, and COVID-19. This has prompted many community and hospital observational studies, which have shown an association between vitamin D deficiency and infection, morbidity, and mortality, and which are supported in the pooled data from metaanalysis. There have been several studies, which have investigated the effect of treatment in the context of COVID-19, though these differ in the population assessed (community or hospital), severity of disease (asymptomatic/mild or moderate/severe), and treatment regime used (bolus or daily regime). None have shown a difference in clinical outcomes other than one pilot RCT, which had methodological flaws. There is therefore insufficient evidence to recommend vitamin D supplement solely for prevention or treatment of COVID-19. There are further RCTs that seek to investigate further, and more understanding on mechanisms of vitamin-D in COVID-19 infection may help direct further therapy to prevent/ameliorate disease.

## 12. Summary points

- There are two different uses for vitamin D in acute respiratory infection, as a nutrition supplement in prevention and as a potential drug for treatment.
- There are a number of mechanisms by which vitamin D could have both a protective antiviral effect and an antiinflammatory effect in limiting the severity of COVID-19 infection.
- Observational data have shown an association between vitamin D status and COVID-19 infection rates, severity, and mortality.
- Several studies have investigated the effect of vitamin D nutritional supplementation on COVID-19; those showing a benefit on clinical outcomes have significant methodological flaws with larger RCTs showing no clear benefit.
- There is currently insufficient evidence to recommend overall vitamin D supplementation solely for prevention of COVID-19; however, the data on use of calcifediol in particular for treatment in improving the outcome of COVID-19 is encouraging.
- Further RCTs seek to investigate effect of vitamin D supplementation on COVID-19.

# Vitamin D and type 1 diabetes

Pieter-Jan Martens, Conny Gysemans and Chantal Mathieu

Clinical and Experimental Endocrinology (CEE), KU Leuven, Leuven, Belgium

## OBJECTIVES

- Present the association between vitamin D deficiency and type 1 diabetes.
- Describe the relation between vitamin D–related genes and the genetic predisposition to type 1 diabetes.
- Discuss the influence of vitamin D on the beta cell and the immune system in both animal models and human trials and describe the underlying mechanism of action.
- Describe the current vitamin D analogs used in type 1 diabetes.
- Discuss the role of vitamin D in combination therapy for type 1 diabetes.

## 1. Introduction

Type 1 diabetes (T1D) remains the most common chronic immune-mediated disease in young children and adolescents. T1D is an autoimmune disorder, characterized by the destruction of the insulin-producing beta cells in the pancreas by the body's own immune system [1]. Despite a clear genetic predisposition, the initial culprit that sets the disease into motion remains unknown. The longstanding classical hypothesis proposes that activation of the immune system results in a rapid destruction of healthy pancreatic beta cells [2]. This dogma is being challenged in recent years with a

conversion to abnormal pancreatic beta cells as initial culprit [3]. This implies that a dysfunctional beta cell is cleared by a normal functioning immune system. As both roads to beta cell destruction remain plausible, the harmonizing hypothesis states that T1D is the result of a complex network of dysfunctions in both the beta cells and the immune system [4]. Nevertheless, in all hypotheses, the true quest remains to determine the initial trigger of the dysfunctional beta cells and/or immune system. Much of the etiology of T1D is accounted for by genetic predisposition. Initially, linkage studies revealed the contribution of the major histocompatibility complex (MHC) to T1D susceptibility [5]. Later, genome-wide association studies increased the number of loci known to be associated with T1D exponentially with some genes linked to beta-cell dysfunction and others to immune cell dysfunction [6]. However, the increased incidence of T1D over the past decades cannot solely be explained by genetics, but is probably related to one or more environmental factors. Of these, vitamin D is one of the most intriguing molecules, as the vitamin D receptor (VDR) has been described in the majority of immune and metabolic cell types involved in the pathogenesis of T1D [7–9]. In this chapter, the correlations between polymorphisms in the VDR or vitamin D metabolic enzymes and risk for T1D will be addressed. The main effects of vitamin D, via its activated form 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>), on the beta cell, with direct implications for the pathogenesis and prevention of T1D will be described and discussed. Furthermore, the role of vitamin D and 1,25(OH)<sub>2</sub>D<sub>3</sub> in the prevention of T1D and its effects on the immune system of the animal models for the disease will be covered.

## 2. Effect of vitamin D deficiency on type 1 diabetes presentation

In humans, the association between serum levels of 25-hydroxyvitamin D<sub>3</sub> (25(OH)D<sub>3</sub>) and T1D seems unequivocal, as T1D incidence is affected both by seasonal variation (increased prevalence in children born in spring) and by latitude (higher prevalence in northern countries with less UVB radiation) [10,11]. In NOD mice, it was reported that 25(OH)D<sub>3</sub> deficiency in utero and early life increases the risk for diabetes development [12]. Also in humans, it was reported that individuals with low preclinical 25(OH)D<sub>3</sub> levels have an increased risk to develop T1D [13]. Based on these promising results, large birth cohort studies that have invited participants based on an increased genetic risk for T1D have analyzed the association between serum 25(OH)D<sub>3</sub> levels and T1D. The Finnish Diabetes Prediction and Prevention (DIPP) study [14,15], the Diabetes Auto-Immunity Study in the Young (DAISY) [16], and the Trial to Reduce IDDM in the Genetically at Risk (TRIGR) [17] all concluded that there was no association between serum 25(OH)D<sub>3</sub> levels and risk of islet autoimmunity or T1D at birth or during childhood. The TRIGR did report that 25(OH)D<sub>3</sub> levels 18 months prior to the age of first seroconversion were lower compared with healthy controls; however, mean 25(OH)D<sub>3</sub> levels remained sufficient ( $\geq 50$  nmol/L) in all groups [17]. On the other hand, The Environmental Determinants of Diabetes in the Young (TEDDY) did report that higher mean 25(OH)D<sub>3</sub> levels in childhood and early infancy were associated with a decreased risk of islet autoimmunity [18]. Being vitamin D sufficient ( $\geq 50$  nmol/L) in childhood was associated with a 31% lower risk of islet autoimmunity compared with those that were insufficient. Vitamin D sufficiency during early infancy was associated with a 40% lower risk of islet autoimmunity compared with those who were insufficient. Recently, a dose–response metaanalysis of case–control studies examining the relation between 25(OH)D<sub>3</sub> levels and the risk of T1D reported a U-shaped association [19]. The risk of T1D descended with 25(OH)D<sub>3</sub> levels ranging from 39 to 89 nmol/L was unchanged when 25(OH)D<sub>3</sub> levels reached 103–113 nmol/L and slightly ascended when 25(OH)D<sub>3</sub> levels surpassed 150 nmol/L.

Vitamin D deficiency during pregnancy may represent a predisposing factor for the development of various autoimmune disorders, including T1D, in later life [20]. A case–control study indicated an association between lower maternal 25(OH)D<sub>3</sub> serum levels during late pregnancy and an increased risk of T1D development in the offspring [21]. However, others reported that maternal midpregnancy or neonatal cord blood 25(OH)D<sub>3</sub> levels did not have an impact on the risk of childhood T1D [15,22,23]. A metaanalysis of case–control studies examining the relation between maternal

25(OH)D<sub>3</sub> levels during pregnancy and the risk of T1D in the offspring reported that lower maternal 25(OH)D<sub>3</sub> levels during pregnancy were associated with a higher risk of T1D in the offspring [24]. Interestingly, no significant association was observed between the 25(OH)D<sub>3</sub> level during first or second gestational trimester and the risk of T1D in the offspring. Although no dose–response analysis was performed, the 25(OH)D<sub>3</sub> levels were within the sufficiency range ( $\geq 50$  nmol/L) in all groups. Not only maternal 25(OH)D<sub>3</sub> levels are potentially associated with T1D development in the offspring, but also maternal vitamin D–binding protein (DBP) levels and the maternal VDR are being investigated as potentially being associated with T1D in the offspring. Indeed, higher maternal DBP levels at delivery, but not in midpregnancy or in the child's cord blood, were associated with a lower risk of T1D in the offspring [25]. Miettinen et al. reported that maternal single-nucleotide polymorphisms (SNPs) in the VDR gene may influence the in utero environment and contribute to the early programming of T1D in the fetus [26]. It is even more complicated as the associations between serum 25(OH)D<sub>3</sub> concentration and some SNPs are stronger during pregnancy in mothers whose children later developed T1D than in mothers whose children did not [27].

Vitamin D deficiency is not only associated with the onset of T1D, but also in people with long-standing T1D, a metaanalysis of multiple observational studies revealed a higher prevalence of vitamin D deficiency compared with healthy controls [28,29].

## 3. Relation between vitamin D–related genes and the genetic predisposition to type 1 diabetes

Novel insights into a possible role of 25(OH)D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub> in the pathogenesis of T1D originate from epidemiological data on associations between polymorphisms of the VDR, vitamin D–metabolizing enzymes *DHCR7*, *CYP2R1*, *CYP27B1*, and *CYP24A1* or the gene for DBP (*GC*), and the risk of T1D in certain ethnic communities.

1,25(OH)<sub>2</sub>D<sub>3</sub> exerts its genomic effects mainly via the nuclear VDR that heterodimerizes with retinoid X receptors and translocates into the nucleus [30] (see Chapters 11–13). VDRs are present in different tissues, including the human pancreatic beta cells and basically every cell of the immune system, and influence important physiological processes such as calcium transport as well as cell growth and differentiation [8]. The gene encoding the VDR is located in humans on chromosome 12q12–14 and has at least two promoter regions, eight protein-coding exons (namely 2–9) and six untranslated exons (1a–1f). It shows extensive SNPs including a FokI polymorphism in exon 2 (rs10735810) that alters the start

codon, BsmI, and ApaI polymorphisms in the intron between exons 8 and 9 (rs1544410 and rs7975232, respectively), a TaqI polymorphism in exon 9 (rs731236), and a polyadenylic acid mononucleotide repeat in the 3' untranslated region [31]. The ApaI and BsmI polymorphisms of the *VDR* gene are considered silent SNPs. These polymorphisms do not alter the amino acid sequence of the encoded protein but seem to be in strong linkage disequilibrium, although there are ethnic variations [32,33]. Besides these frequently studied variants, there are many other polymorphisms that are less often considered, including A1012G (A to G substitution), Cdx2 (rs11568820), and various resulting *VDR* genotype combinations. Several studies showed a correlation between some of these *VDR* polymorphisms and T1D, whereas others failed to confirm this association. A large metaanalysis found an association between BsmI polymorphism and T1D risk in an Asian population, with a 30% increased risk for carriers [34]. A study by Ban et al. revealed an association between FokI polymorphism and GAD65 positivity in a Japanese population [35]. However, the Type I Diabetes Genetics Consortium did not find any association of *VDR* SNPs with T1D in the overall sample set or in any of the subgroup analyses of the parent-of-origin, gender of offspring, and human leukocyte antigen (HLA) risk [36]. Nevertheless, vitamin D receptor response elements exist in the promotor region of at least certain HLA alleles [37]. This indicates that vitamin D metabolism and/or the genetic effects regulated via the *VDR* may be connected with the HLA-related immune response, which may have an impact on the pathogenesis of T1D [38]. This was recently confirmed by Miettinen et al. who reported that women with the HLA-B44 supertype (consisting of B\*18, B\*37, B\*40, and B\*44 alleles) had lower 25(OH)D<sub>3</sub> concentrations [38]. In addition, the FokI polymorphism of the *VDR* could have functional implications, altering ligand-mediated gene expression in beta cells or in the immune system [39]. The function of the other polymorphisms, located in introns of the *VDR*, is unknown but likely involves mRNA stability [40].

The enzymes CYP2R1 (a 25-hydroxylase [25-OHase]) and CYP27B1 (1 $\alpha$ -OHase) catalyze the metabolism of vitamin D<sub>3</sub> to 25(OH)D<sub>3</sub> and 1,25(OH)<sub>2</sub>D<sub>3</sub>, the most active natural vitamin D metabolite, whereas CYP24A1 (24-OHase) is involved in the catabolism and inactivation of 1,25(OH)<sub>2</sub>D<sub>3</sub> through a series of events starting with 24-hydroxylation. Multiple studies show that polymorphisms in the *CYP2R1* gene and in the *CYP27B1* gene located on chromosome 12q13.1-q13.3 are associated with an increased risk of developing T1D [41–44]. These SNPs are assumed to reduce the (local) expression of the 1 $\alpha$ -(OH)ase enzyme and consequently the conversion of 25(OH)D<sub>3</sub> to 1,25(OH)<sub>2</sub>D<sub>3</sub>. Although genetic variants in *CYP24A1* have been shown to associate with

serum 25(OH)D<sub>3</sub> levels [45], no associations with T1D have been found. However, when SNPs at the *DHCR7*, *GC*, *CYP2R1*, and *CYP24A1* loci were combined, there was a cumulative effect on the T1D susceptibility [46]. On the other hand, a large genome-wide association study in European-ancestry individuals showed that common genetic variants are unlikely to have a strong modifying effect on increases in 25(OH)D<sub>3</sub> levels following typical dietary intakes [47]. Based on the SNPs from genes influencing 25(OH)D<sub>3</sub> levels in this study, being *CYP2R1* rs10741657, *CYP2R1* rs117913124, *DHCR7/NADSYN1* rs12785878, *GC* rs3755967, *CYP24A1* rs17216707, *AMDHD1* rs10745742, and *SEC23A* rs8018720, Hyppönen et al. performed a meta-analysis assessing associations between these variants effecting 25(OH)D<sub>3</sub> and T1D risk, revealing a null association [48].

The significance of the potential correlations between genetic contributors to vitamin D metabolism and T1D remains unclear. Nevertheless, an association of *VDR* genotypes with *VDR* mRNA as well as protein has been demonstrated in peripheral blood mononuclear cells providing functional relevance to the *VDR* polymorphisms [49]. Also, a large, nested, case–control study following 8676 children at increased genetic risk of T1D demonstrated not only that the risk of islet autoimmunity depends on the childhood 25(OH)D<sub>3</sub> level, but also that this needs be adjusted by the *VDR* genotype [18]. This was later confirmed by Stene et al. who reported that in children homozygous for the *VDR* rs11568820 G/G genotype, higher 25(OH)D<sub>3</sub> levels at birth predict a decreased risk for T1D [25]. The explanation for this observation given is that *VDR* genotype rs11568820 results in lower *VDR* expression [50].

#### 4. Vitamin D and the beta cell

Since the early observations in 1980 by Norman et al. [51] that pancreatic insulin secretion is selectively inhibited by hypovitaminosis D, several reports have demonstrated an active role for 1,25(OH)<sub>2</sub>D<sub>3</sub> in beta cell function. This is reinforced by demonstration of the presence of the *VDR* [52] in pancreatic beta cells, the expression of 1 $\alpha$ -OHase in pancreatic beta cells [53], and the presence of a vitamin D response element in the human insulin receptor gene promoter [54].

In the pathogenesis of T1D, considerable evidence indicates that the cytotoxic action of proinflammatory cytokines on pancreatic beta cells is mediated through the generation of free radicals and the induction of endoplasmic reticulum stress [55]. Due to their function in insulin synthesis and secretion, beta cells have an elaborate ER system and are thus considered to be under high ER stress. In severe ER stress, the active form of

PERK increases ATF4 expression and subsequently promotes CHOP production. CHOP is a transcription factor that induces the expression of proapoptotic factors [56].  $1,25(\text{OH})_2\text{D}_3$  is able to protect the beta cells against ER stress-associated apoptosis by inhibiting this PERK-ATF4-CHOP pathway [57]. Apoptosis results in the release of beta cell proteins, and these autoantigens can elicit an immune response. Here, DBP has been identified as a T1D autoantigen [58]. The alpha cells of the pancreatic islets are also one of the few tissues outside the liver to express significant levels of DBP [59,60]. In alpha cells, the action of intracellular DBP appears to be independent of its normal systemic cargo  $25(\text{OH})\text{D}_3$  and instead involves a well-recognized function of DBP as an actin binder (see Chapter 7). DBP-induced intracellular changes in actin have been shown to be associated with altered alpha cell morphology, leading, in turn, to modulation of beta cell function [61]. Zhang et al. later confirmed that DBP-specific epitopes elicit cytotoxic T lymphocyte responses and as such contribute to the development of T1D [62].

Inflammation plays a crucial role in T1D pathogenesis, contributing to beta cell dysfunction and apoptosis through cytokines and chemokines produced by immune cells but also by beta cells themselves [63]. In this regard,  $1,25(\text{OH})_2\text{D}_3$  and its analogs have been shown to prevent the interleukin (IL)- $1\beta$ -induced inhibition of beta cell function, as well as interferon (IFN)- $\gamma$ -stimulated beta cell expression of MHC class I and class II molecules in rat pancreatic islets [64,65]. Nevertheless, the exact mechanism by which cytokines act to promote beta cell destruction remains unclear. It has been suggested that inflammatory cytokines predispose pancreatic beta cells to lysis by autoreactive T cells.  $1,25(\text{OH})_2\text{D}_3$  does not provide direct protection against cytokine-induced beta cell death as treatment with  $1,25(\text{OH})_2\text{D}_3$  did not protect purified beta cells against cytokine-induced cell death [66]. However, Wolden-Kirk et al. showed that  $1,25(\text{OH})_2\text{D}_3$  could almost completely prevent cell death induced by inflammatory cytokines IL- $1\beta$  and IFN- $\gamma$  in human and mouse whole islets, while restoring impaired insulin secretion.

Protection of beta cells by  $1,25(\text{OH})_2\text{D}_3$  is accompanied by altered expression of genes involved in chemotaxis, cell death, and beta cell function [67]. Another observation is that  $1,25(\text{OH})_2\text{D}_3$  is not only able to alter the effect of cytokines on beta cell function, but also blocks the induction of beta cell surface markers by these cytokines. When neonatal rat islets were incubated with T helper (Th)-1 IFN- $\gamma$ , several surface markers, including those linked to antigen presentation such as MHC-II molecules, were upregulated, making them better targets for the immune system. Coincubating the islets with  $1,25(\text{OH})_2\text{D}_3$  or some of its analogs markedly

decreased the upregulation of MHC-II molecules after IFN- $\gamma$  stimulation [65]. Moreover, treatment of beta cells with  $1,25(\text{OH})_2\text{D}_3$  is able to directly protect against proinflammatory cytokine-induced beta cell death by reducing the density of MHC class I molecules [65], reducing IL-6 production and nitric oxide synthesis [68], inducing the expression of antiapoptotic A20 protein [69], and decreasing the expression of Fas [70]. Wei et al. [71] recently reported that association of the VDR with the alternative chromatin-remodeling complex PBAF enhances the VDR-dependent transcriptional program, resulting in reduced cytokine-induced beta cell proinflammatory response and preserved beta cell function in human beta-like cells and in diabetic mouse models. Complementing these findings, we observed that exposure to  $1,25(\text{OH})_2\text{D}_3$  in three cell systems (e.g., INS-1E beta cell line, FACS-purified rat beta cells, and nonobese diabetic (NOD)-severe combined immune-deficient islets) suppressed chemokine CXCL10 and IL-15 expression in the beta cell itself but did not prevent cytokine-induced beta cell death [66]. These data show beta cell protection against inflammatory agents involved in the pathogenesis of T1D and thus may have direct implications for the observed in vivo effects of  $1,25(\text{OH})_2\text{D}_3$  and its analogs in the prevention of T1D in animal models and humans. Vitamin D (metabolites) make beta cells less visible to the immune system (cell surface markers) and reduce the attraction signals for the immune system secreted by beta cells themselves.

The influence of vitamin D on beta cells was further tested in animal models of T1D such as the spontaneously diabetic NOD mouse model and the streptozotocin (STZ)-induced mouse model of T1D. A remarkable observation in the NOD mouse is that *Vdr* gene expression is decreased in islets of mice that develop diabetes [72]. Overexpression of *Vdr* is able to ameliorate diabetes in transgenic NOD mice by increasing the proliferation capacity of the beta cell and by reducing local inflammation as the antiinflammatory A20 mRNA was increased and the proinflammatory *Tnfa*, *Tgfb*, and *H2Aa* mRNA levels were decreased compared with control [72]. Moreover, vitamin D seems to have an effect on cathepsin G (CatG). CatG is the only protease involved in the antigen presentation of proinsulin, and a CatG-specific inhibitor can improve the beta cell function by a reduced activation of  $\text{CD4}^+$  T cells, thus slowing the progression of diabetes in NOD mice [73]. Lai et al. reported that vitamin D supplementation also functions as CatG inhibitor in diabetic NOD mice as it is able to improve beta cell function by a downregulation of CatG and thus inhibition of  $\text{CD4}^+$  T cell activation [74].

In the STZ mouse model, a single high dose of STZ (70–250 mg/kg body weight) causes a rapid and

complete destruction of beta cells. On the other hand, multiple lower doses of STZ (e.g., 50 mg/kg on five consecutive days) cause more subtle beta cell damage followed by insulin deficiency model [75]. In the low doses of STZ model, treatment with  $1,25(\text{OH})_2\text{D}_3$  reduced diabetes incidence from 85% to 45% [76]. In a study of Inaba et al., both the high- and the low-dose models of STZ were used to test the effect of  $1\alpha\text{-(OH)D}_3$ , a precursor of  $1,25(\text{OH})_2\text{D}_3$ , on diabetes prevention [77]. The rationale for utilizing  $1\alpha\text{-(OH)D}_3$  is that this will be hydroxylated in the liver to generate the bioactive  $1,25(\text{OH})_2\text{D}_3$  compound in vivo. In the single high-dose STZ model, no protection against diabetes was observed with  $1\alpha\text{-(OH)D}_3$ . When multiple low doses of STZ were administered,  $1\alpha\text{-(OH)D}_3$  reduced the diabetes incidence dramatically to 46% compared with 100% in control mice. Histological examination of the pancreas of these experimental mice demonstrated that  $1\alpha\text{-(OH)D}_3$  also reduced insulinitis. A major criticism of this model remains the fact that the beta cell destruction is probably the result of nonspecific inflammatory damage and not a true (auto)immune-mediated model for diabetes [78]. Indeed, disease progression is not dependent on the presence of an autoimmune response because STZ is able to induce diabetes even in the absence of functional T and B cells. Furthermore, in this STZ-induced model, it was also demonstrated that  $1,25(\text{OH})_2\text{D}_3$  injections protected beta cells against apoptosis and reversed insulinitis by autophagy [79], which is essential for the survival and function of the beta cells [80]. Here,  $1,25(\text{OH})_2\text{D}_3$  was able to enhance the expression of LC3 and Beclin 1, essential proteins involved in autophagy, and therefore accelerate the renewal of organelles under stress, together with an increased expression of the antiapoptotic protein Bcl-2 [79].

## 5. Vitamin D as an immune modulator in type 1 diabetes

The VDR is present on almost every cell of the immune system, including macrophages, dendritic cells (DCs), and activated B and T cells, allowing them to respond to the active ligand [8] (see Chapters 94–96). Therefore, a physiological role for  $1,25(\text{OH})_2\text{D}_3$  as a potential immune regulator is reasonable, and so far, many studies yielded beneficial results using active vitamin D to prevent and/or intervene in different autoimmune disease models including T1D [81,82]. Results in autoimmune diabetes-prone NOD mice are promising, but many obstacles to human application still exist. Clinical application of  $1,25(\text{OH})_2\text{D}_3$  is hindered by toxicity because the supraphysiological doses needed to shape the immune system also elicit hypercalcemic side

effects. All studies involving long-term immune suppression are inconceivable as strategy for the prevention of a chronic disease in children and adolescents. Moreover, preliminary results on the beneficial effects of these drugs in recent-onset diabetic subjects have been disappointing [83–85].

Interestingly, most of the aforementioned immune cells are able to convert  $25(\text{OH})\text{D}_3$  into  $1,25(\text{OH})_2\text{D}_3$  as they express the *CYP27B1* gene ( $1\alpha\text{-OHase}$ ) (see Chapter 9), while DCs also express a  $25\text{-OHase}$  [86,87]. Local processing of vitamin D precursors into the bioactive metabolite may represent an important mechanism by which immune cells can reach these supraphysiological levels of  $1,25(\text{OH})_2\text{D}_3$  inside the cell without negative feedback by  $1,25(\text{OH})_2\text{D}_3$  itself [86]. This mechanism results locally in high concentrations, which are needed to modulate immune responses autonomously, without changing the systemic concentrations of this hormone [88]. These intracrine, autocrine, and paracrine signaling events are critically dependent on sufficient  $25(\text{OH})\text{D}_3$  levels available to the cell as substrate for the  $1\alpha\text{-OHase}$ . This was recently illustrated by Th1 cells expressing *CYP27B1*. Here, an autocrine/paracrine loop permits Th1 cells to both activate and respond to vitamin D as part of a shutdown program repressing  $\text{IFN-}\gamma$  and enhancing IL-10 [89]. Based on these findings, supplementation with vitamin D represents an attractive strategy to overcome vitamin D deficiency and ensure adequate immune cell function. Nevertheless the effect of vitamin D on immune cells is complex as illustrated by the fact that VDR expression in immune cells (e.g., T cells or monocytes) is sometimes differently controlled according to the corresponding activation status [90,91].

## 6. Interventions using vitamin D to prevent or arrest type 1 diabetes

### 6.1 Animal studies

The NOD mouse and biobreeding (BB) rat are the two most commonly used animals that spontaneously develop diabetes, comparable with human type 1 diabetes [92]. As such are these models crucial in providing insights into genetic susceptibility and mechanisms of disease pathogenesis, but also in the translational development of novel therapies [93]. It was in fact in the NOD mouse model in which it was first demonstrated that chronic administration of pharmacological doses of  $1,25(\text{OH})_2\text{D}_3$  can reduce the incidence of both insulinitis (the histological lesion of diabetes) and diabetes [94,95].

In these prevention trials, the timing and product of the vitamin D supplements turned out to be crucial. Regardless of the dosing regimen or type of vitamin D product used, only early and long-term treatment

prevented diabetes in NOD mice [66,96]. In the life of a NOD mouse, weaning is at 3 weeks of age, and insulinitis (the immune infiltration of the islets of Langerhans, and thus histological reflection of beta cell attack) starts at 6–8 weeks of age. Diabetes onset starts from 10 weeks of age, with a peak at 14–16 weeks of age, and can occur until 30 weeks of age. Vitamin D intervention from 14 weeks of age (i.e., in the presence of insulinitis) failed to prevent disease [66]. This implies treatment must be started early. A relevant question is if long-term treatment with  $1,25(\text{OH})_2\text{D}_3$  is necessary for disease protection or if a short-term intervention would suffice. If so, when in the course of the disease should this short-term treatment be given? Vitamin D from 3 weeks of age until 14 weeks of age is able to reduce diabetes onset, but is inferior compared with a lifelong continuation of the intervention [66,96]. This is exemplified by Gysemans et al. [66] showing a reduction of diabetes from 58% in control NOD mice compared with 20% in NOD mice treated lifelong with  $1,25(\text{OH})_2\text{D}_3$  or to 35% in mice treated only until 14 weeks of age. Others also reported that vitamin D (16 IU by gavage) administered in utero (via the mother), and the first 10 weeks of life did not change the incidence of diabetes or modify the disease processes that leads to beta cell destruction in the NOD mouse [97].

Besides timing, the type of product and the dosing regimen of the vitamin D supplements are also crucial. Animal studies are essential in the exploration of the product and dosing regimen in vitamin D interventions as they bridge in vitro research with human trials. In vitro research is often an artificial situation, with continued exposure of the immune cell subsets to (often supraphysiological) high doses of vitamin D products, mostly  $1,25(\text{OH})_2\text{D}_3$  [9]. These concentrations are often not achievable in human peripheral blood but could potentially be reached at local sites of inflammation as many immune cells can produce vitamin D metabolites themselves upon activation [8,98].  $1,25(\text{OH})_2\text{D}_3$ , the active form of vitamin D, reduces the diabetes incidence in NOD mice when given either intraperitoneally at  $5\text{ }\mu\text{g/kg}$  body weight every other day [66,95] or orally via incorporation of the hormone in the diet ( $50\text{ ng/day}$ ) [99]. However, these interventions resulted in increased serum calcium levels, increased bone turnover (reflected in serum osteocalcin levels), and bone loss. A caveat in these studies is that many dietary changes can have an effect on the disease incidence as exemplified by Zella et al. [99] where the diet besides being enriched in  $1,25(\text{OH})_2\text{D}_3$  was also low calcium. This resulted in an unusually low spontaneous disease incidence in the control mice. When mice were given a normal-calcium full-grain diet,  $1,25(\text{OH})_2\text{D}_3$  treatment did not reduce diabetes incidence to previously reported levels, but control mice had a normal spontaneous disease incidence [100].

As most cells of the immune system have the appropriate machinery to process vitamin  $\text{D}_3$  into its bioactive compound, natural vitamin  $\text{D}_3$  may ultimately be more desirable for clinical use [8]. Here, in contrast to  $1,25(\text{OH})_2\text{D}_3$ , the method of administration seems to make a difference. Peritoneal injection of 1000 IU/day of solubilized vitamin  $\text{D}_3$  from 3 to 70 days of age was unable to provide protection against diabetes development in NOD mice by 30 weeks of age [101]. However, it must be taken into account that treatment was not given lifelong. In contrast, lifelong dietary supplementation with a high-dose vitamin  $\text{D}_3$  (800 IU/day) from weaning to 35 weeks of age did significantly reduce diabetes incidence with 52% (females) and 58% (males) in NOD mice [96]. No calcium toxicity was observed, while pancreatic insulin content was preserved and the insulinitis score improved.

In immune-mediated diseases, vitamin D results in a shift in the immune status toward the induction of tolerance and is as such appealing as an immune modulator in immune-mediated diseases [9]. In the NOD mouse model, the basis for interference with the immune response was found to be by restoration of the suppressor cell function [95]. Later, it was demonstrated that the nature of the suppressor cell induced by both  $1,25(\text{OH})_2\text{D}_3$  and vitamin  $\text{D}_3$  is most likely a  $\text{CD4}^+$  regulatory T cell (Treg) [96,102]. Tregs, characterized by a combination of surface markers including CD25, CD103, CTLA-4, CD62L, glucocorticoid-induced tumor necrosis factor (TNF) receptor family-related protein, glycoprotein-A repetitions predominant, and by expression of the forkhead/winged helix transcription factor (FoxP3), have been implicated as key players in immune tolerance (see Chapter 96). The key role of Tregs in diabetes occurring in NOD mice has been confirmed by cyclophosphamide (CTX). CTX administration induces diabetes in NOD mice due to a reduction in naturally occurring Tregs [103,104]. Shortly after CTX treatment,  $\text{CD4}^+\text{CD25}^+$  Tregs are functionally impaired in their suppressive activity and display higher levels of apoptosis [103]. While cell numbers recover in lymphoid tissues immediately before onset of diabetes, frequencies of Tregs in the pancreas remain low.

Several potential preventive therapies have already been tested in this CTX model of T1D, as this model is able to determine if protection against diabetes by therapeutic interventions is only by the induction of suppressor T cells and not by autoreactive T cells [105,106]. Casteels et al. used this model and demonstrated that  $1,25(\text{OH})_2\text{D}_3$  can prevent diabetes induced by CTX in the NOD mouse [107]. Insulinitis was significantly reduced from 100% in control NOD mice to 42% in  $1,25(\text{OH})_2\text{D}_3$ -treated NOD mice, whereas diabetes itself was reduced from 78% to 17%. As such, protection was achieved despite a total elimination of

immunosuppressive cells in the  $1,25(\text{OH})_2\text{D}_3$ -treated group by CTX (as shown by cotransfer experiments).  $1,25(\text{OH})_2\text{D}_3$  treatment also did not interfere with the quantitative and qualitative recovery of the major lymphoid-hematopoietic cells after CTX administration. Striking was the absence of insulitis in most animals treated with  $1,25(\text{OH})_2\text{D}_3$ . Both the resistance against CTX and reduction of insulitis together with the absence of protection in cotransfer experiments suggested that CTX had eliminated Tregs. It appears that these suppressive cells are not the sole protective mechanism in the vitamin D-treated NOD mice. It is reported that also  $\text{CD11b}^+\text{Ly6G}^-\text{Ly6C}^+$  monocytes might contribute to the adjuvant effect of CTX, but no data are available on the effects of  $1,25(\text{OH})_2\text{D}_3$  on this myeloid cell population and its immunosuppressive capacities [108]. Furthermore, Takiishi et al. reported that vitamin  $\text{D}_3$  supplementation decreases effector  $\text{CD8}^+\text{IFN-}\gamma$  and  $\text{CD4}^+\text{IFN-}\gamma$  T cells [96].

The BB rat is another spontaneous animal model for T1D. In this model, no difference in diabetes incidence between control (20%) and  $1,25(\text{OH})_2\text{D}_3$ -treated rats (29% and 39%) was observed, while  $1,25(\text{OH})_2\text{D}_3$  (0.2 or 1  $\mu\text{g}/\text{kg}/2$  days, respectively) was administered from 3 to 50 days of age [101]. In this model, also vitamin  $\text{D}_3$  (1000 IU/day) was not able to prevent diabetes by early-life treatment (from 3 to 50 days of age) [101].

## 6.2 Human studies

Based on previous observations, the association between vitamin D and T1D seems unequivocal, and vitamin D deficiency is postulated as one of the potential triggers of T1D onset. However, even more than in animal studies, the design of human trials is hampered by uncertainty of product choice, timing of intervention, and dosing regimen [9]. It has to be taken into account that even the definition of vitamin D insufficiency and deficiency is based on the skeletal effects of vitamin D, and these definitions may not apply to levels needed for normal functioning of beta cells or the immune system (see Chapters 51 and 52) [109].

T1D is a disease affecting young children and adolescents, necessitating interventions early in life when prevention of the disease is attempted. Intervention trials in animal studies, as described earlier, have demonstrated that early and lifelong interventions can prevent T1D onset [95,96]. In humans, several trials intervened already during pregnancy by optimizing the maternal intake of vitamin D [110,111]. Here, Stene et al. demonstrated that cod liver oil taken during pregnancy can reduce T1D in offspring. Fronczak et al. as part of the DAISY recruitment trial, confirmed that

maternal intake of vitamin D through food during pregnancy was associated with a decreased risk of islet autoimmunity in offspring [112]. Not all reports come to the same conclusion, however, as Virtanen et al. did not find a correlation between maternal intake of vitamin D during pregnancy and the risk for the development of diabetes-associated autoantibodies or clinical T1D in the offspring [111]. A possible reason for this discrepancy is that the latter was a retrospective trial, which is subject to recall bias. Despite these mixed results, Sorensen et al. found a clear association between low  $25(\text{OH})\text{D}_3$  levels during pregnancy and an increased risk for T1D [21]. Here, blood samples were mainly taken in the last trimester of the pregnancy and demonstrated that children born from a mother with a  $25(\text{OH})\text{D}_3$  level of  $\leq 54$  nmol/L had a more than twofold risk of developing T1D compared with children born from a mother with a  $25(\text{OH})\text{D}_3$  level of  $> 89$  nmol/L.

Several trials reported an association between vitamin D supplementation early in life, even already starting during the first year of life, and a decreased risk for T1D [113–117]. A metaanalysis of data from four case–control studies revealed that children being supplemented with vitamin D had a 29% reduction in the risk of developing T1D compared with unsupplemented controls [116]. The optimal timing of the intervention remains unclear, but is suggested to be more beneficial from 7 to 12 months of age than supplementation from birth to 6 months of age [113]. The dosing regimen and product of supplementation remain uncertain. In the majority of these studies, no information was given about the dosing regimen or product that was used [116]. On the other hand, Hypponen et al. reported that the intake of 2000 IU vitamin  $\text{D}_3$  during the first year of life diminished the risk of developing T1D [115]. Here, the authors showed some evidence of a dose–response and regularity effect, with those using higher and more frequent amounts of vitamin D being at lower risk of developing T1D. Taking into account that T1D susceptibility is linked to specific HLA genotypes, Wicklow and Taback intended to pursue a trial using 2000 IU/day of cholecalciferol in newborn babies with increased HLA-associated risk [117]. Although the dose was found to be safe, the clinical trial addressing the effect of cholecalciferol supplementation on T1D risk in newborns has not yet been initiated. However, in a small prospective trial, 12 high-risk children, aged 1.5–13 years old, with islet cell autoantibodies were supplemented with oral calcitriol (0.25  $\mu\text{g}/\text{day}$ ) for 1–3 years. Here,  $1,25(\text{OH})_2\text{D}_3$  was able to decrease serum autoantibody levels against GAD65 and insulin in all participants, suggesting to be effective in the prevention of T1D [118].

Besides its impact as environmental trigger in T1D and thus its role in the prevention of T1D, vitamin D has meaningful immunomodulatory characteristics [9]. This warrants its use in new-onset (and potentially established) T1D to help preserve the residual beta cell function. A retrospective analysis in children and adolescents newly diagnosed with T1D indeed reported that low 25(OH)D<sub>3</sub> levels are related to a higher HbA1c at diagnosis and that if these individuals did not receive supplementation, there was a worse glycemic control versus those with baseline repletion [119]. Here, researchers face the same problems, being the uncertainty about timing, product, and dosing regimen of the vitamin D intervention. As a rule of thumb, the earlier the intervention, the more residual beta cell function is to be saved in newly diagnosed T1D. With regard to the product of intervention, clinical data on the use of 1,25(OH)<sub>2</sub>D<sub>3</sub>, starting when the decline of beta cell function is already ongoing, are disappointing. A small intervention trial, in which new-onset diabetic children were given a small dose of 1,25(OH)<sub>2</sub>D<sub>3</sub> (0.25 µg/2 days), showed that there was no improvement of C-peptide levels, although insulin requirements decreased in the 1,25(OH)<sub>2</sub>D<sub>3</sub>-treated group [83]. An increase of the dose to 0.25 µg 1,25(OH)<sub>2</sub>D<sub>3</sub> (probably the maximum tolerable dose) was tested in two intervention trials [84,85], but both showed no protective effect on the residual beta cell function as C-peptide, fasting C-peptide, HbA1c, and insulin requirement were all comparable with the control group. Even when specified in recent-onset patients with high basal C-peptide levels, no protective effect was observed [84]. In contrast to these unsuccessful interventions with 1,25(OH)<sub>2</sub>D<sub>3</sub>, interventions with vitamin D<sub>3</sub> did show some protection. A potential reason for this is that interventions with vitamin D<sub>3</sub> allow the use of higher dosing regimens without a significant risk of hypercalcemia. Here, interventions with 2000 IU/day for 18 months [120] or 140,000 IU/month for 3 months [121] did show a slower decline of C-peptide levels compared with the control group. An intervention with 50,000 IU/week for 2 months and then 50,000 IU/biweekly for 10 months did not show differences compared with the control group after 12 months [122]. However, in the vitamin D<sub>3</sub> intervention group, there was a decreased rate of increase in both HbA1c and insulin dose-adjusted HbA1c.

To avoid enrollment during the honeymoon period, when C-peptide concentrations may remain variable regardless of the intervention, Panjiyar et al. decided to intervene in T1D patients 1–2 years postdiagnosis with 3000 IU/day vitamin D<sub>3</sub> for 1 year [123]. In the vitamin D<sub>3</sub> intervention group, there was a decrease in fasting blood glucose level, HbA1c, and stimulated C-peptide compared with the control group.

Moving further along the timeline of disease progression, also in people with long-standing T1D, the impact of optimizing vitamin D levels on the glucometabolic control has been explored. Interventions in long-standing T1D with 4000 IU/day [124], 10,000 IU/day [125], or 50,000 IU biweekly [126] vitamin D<sub>3</sub> resulted in an improved glucometabolic control with a reduction in HbA1c, insulin demands, fasting blood sugar levels, lower glycemic variability, and a lower frequency of hypoglycemia. Despite promising data, not all trials come to the same conclusion. Some did not find an improvement in glucometabolic control by interventions with 4000 IU/day [127], 10,000 IU/day [127], or monthly doses of 60,000 IU to 120,000 IU vitamin D<sub>3</sub> [128]. Nevertheless, vitamin D-insufficient patients with long-standing T1D had a similar therapeutic response to single dose of 150,000 IU vitamin D<sub>3</sub> as healthy controls with similar baseline 25(OH)D<sub>3</sub> levels [129]. This suggests that insulin deficiency alone does not significantly affect either the regulation of vitamin D metabolism or the activity of the enzymes involved. It is possible that the immunomodulatory effects of vitamin D<sub>3</sub> only occur at optimal serum concentrations maintained for a sufficiently long period to achieve protection on the residual beta cell function. This is a plausible hypothesis, explaining why certain studies using bolus doses of vitamin D<sub>3</sub> do not produce appreciable benefits on residual beta cell function [123].

Finally, vitamin D supplementation has been explored in latent autoimmune diabetes in adults (LADA). This is a subtype of T1D in which the clinical manifestations begin in adulthood and progress slowly. Patients with LADA who received 1α-(OH)D<sub>3</sub>, the synthetic precursor of 1,25(OH)<sub>2</sub>D<sub>3</sub>, exhibited a partial preservation of beta cell function in comparison with patients treated with insulin alone [130].

## 7. Immune effects of interventions with vitamin D in type 1 diabetes

At present, the proposed basis of protection by interventions with vitamin D and its metabolites seems to be a reshaping of the immune repertoire next to protective beta cell effects (Fig. 100.1). In general, vitamin D induces a more tolerogenic immune environment. Its regulatory actions involve a shift in T cell cytokine profiles from predominantly proinflammatory Th1 (e.g., IL-2, IFN-γ, and TNF-α) and Th17 (e.g., IL-17) to antiinflammatory Th2 (e.g., IL-4, IL-10) profiles [102,131]. In addition, 1,25(OH)<sub>2</sub>D<sub>3</sub> directly promotes the generation of IL-10-producing Tregs [132,133]. This was later confirmed in both animal [96] and human [134] trials. These Tregs were found to have an enhanced suppressive capacity as defined by the reduction of effector

**FIGURE 100.1** At the level of the DC, 1,25(OH)<sub>2</sub>D<sub>3</sub> inhibits the surface expression of MHC-II and of costimulatory molecules as well as the production of the cytokine IL-12 (and IL-23), together with a stimulation of IL-10 and TNF-α, thereby indirectly shifting the polarization of T cells from a Th1 toward a Th2 phenotype. In addition, 1,25(OH)<sub>2</sub>D<sub>3</sub> acts as immune modulator directly at the level of the T cell by inhibiting the production of the Th1 cytokines IL-2 and IFN-γ (red arrows), Th17 cytokine IL-17 while stimulating the production of Th2 cytokines such as IL-4, IL-5, and transcription factors GATA-3 and c-MAF (green arrows). Moreover, 1,25(OH)<sub>2</sub>D<sub>3</sub> favors the induction of regulatory T cells (Tregs). 1,25(OH)<sub>2</sub>D<sub>3</sub> also improves chemotactic and phagocytic capacity of macrophages. Adapted from [8].

T cells proliferation [121]. In a study comparing T1D subsets with their healthy siblings, Savastio et al. reported in the healthy individuals that low levels of 25(OH)D<sub>3</sub> allow expansion of Th17 cells that may be counteracted by increased Treg/ICOS<sup>+</sup> levels by vitamin D supplementation [135]. This was particularly seen in healthy siblings carrying protective haplotypes as they showed the highest levels of Treg/ICOS<sup>+</sup> cells without substantial differences in Th17 after vitamin D supplementation, while T1D subsets did not display this expansion of Treg/ICOS<sup>+</sup> cells. This suggests that vitamin D is unable to act when the disease is already established in T1D, indicating that supplementation could be more useful in the prevention phase before the beta cell destruction.

In addition to its direct actions on T cells [90], 1,25(OH)<sub>2</sub>D<sub>3</sub> can also modulate T cell responses indirectly via effects on antigen-presenting DC [136,137]. Indeed, 1,25(OH)<sub>2</sub>D<sub>3</sub> is able to reshape DCs toward

tolerogenic cells with reduced expression of antigen-presenting and costimulatory molecules as well as proinflammatory cytokines, thereby affecting the DC-T cell stimulatory capacity resulting in T cell anergy and the induction of antigen-specific Tregs [138–144]. In human monocyte-derived DCs, induction of the tolerogenic profile by 1,25(OH)<sub>2</sub>D<sub>3</sub> is accompanied by an early metabolic reprogramming [145,146]. This metabolic reprogramming is unique for 1,25(OH)<sub>2</sub>D<sub>3</sub> and favors oxidative phosphorylation, which is accompanied by increased aerobic glycolysis. The result is that 1,25(OH)<sub>2</sub>D<sub>3</sub>-conditioned fully differentiated DCs, but not tolerogenic DCs induced by other biological and pharmacological agents, rely on glucose availability and usage, as well as on the PI3K/Akt/mTOR pathway, for the induction and maintenance of their tolerogenic phenotype [146] (Fig. 100.2). The glycolytic enzyme 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 4 (PFKFB4) is a critical checkpoint in this process as

**FIGURE 100.2** 1,25(OH)<sub>2</sub>D<sub>3</sub> reshapes DCs toward a more tolerogenic profile by the activation of the glucose metabolism in these cells. This is unique for 1,25(OH)<sub>2</sub>D<sub>3</sub> and implies that 1,25(OH)<sub>2</sub>D<sub>3</sub>-conditioned fully differentiated DC, but not tolerogenic DCs induced by other biological and pharmacological agents, rely on glucose availability and glycolysis controlled by the PI3K/Akt/mTOR pathway, for the induction and maintenance of their tolerogenic phenotype and function. The glycolytic enzyme 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 4 (PFKFB4) is a critical checkpoint in this process. *Original figure from [146].*

inhibition of this enzyme blocks 1,25(OH)<sub>2</sub>D<sub>3</sub>-conditioned DCs' capacity to induce suppressive Tregs [147]. Epigenetic modifications further contribute to the stability of tolerogenic DCs, as they are able to persist perturbation by inflammatory stimuli [148,149]. Although these two studies found that about a third of the transcripts encoded by non-HLA T1D were differentially between inflammatory DCs and 1,25(OH)<sub>2</sub>D<sub>3</sub>-conditioned DCs, only five of these genes were direct targets of the VDR. The understanding these genetic risk loci holds the potential to develop specific or selective disease intervention strategies [150]. In vivo, it has been demonstrated that DCs generated in the presence of 1,25(OH)<sub>2</sub>D<sub>3</sub> can redirect already committed T cell clones derived from a T1D patient toward nonproliferation [140]. In the NOD mouse, reshaping of the immune system happens centrally, in the thymus, where treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> restores the sensitivity of T lymphocytes toward apoptosis-inducing signals, allowing only "activation-induced cell death"—sensitive T cells

to reach the periphery [107,151,152]. In vivo transfer of islet antigen-loaded 1,25(OH)<sub>2</sub>D<sub>3</sub>-modulated DCs could successfully prevent islet allograft rejection [144]. Moreover, their in vivo migratory capacity remained intact and favored homing to the pancreas of adult NOD mice [143].

## 8. Vitamin D analogs and type 1 diabetes

A major obstacle to the human application of 1,25(OH)<sub>2</sub>D<sub>3</sub> is its adverse effects on calcium and bone metabolism. New structural analogs of 1,25(OH)<sub>2</sub>D<sub>3</sub> have been reported, displaying a clear dissociation of calcemic and antiproliferative effects [153,154]. Some chemical modifications of the side chain and A-ring results in "superanalogs" with 10–100-fold more activity on cell differentiation and the immune system than native 1,25(OH)<sub>2</sub>D<sub>3</sub>. Nonsteroidal analogs of 1,25(OH)<sub>2</sub>D<sub>3</sub>, lacking either the full five-membered D-

ring (C-ring analogs) or the full six-membered C-ring (D-ring analogs), are designed and documented to be very effective inhibitors of cell proliferation or inducers of cell differentiation than is  $1,25(\text{OH})_2\text{D}_3$  [154,155]. Interestingly, several of the vitamin D analogs possess more potent immunomodulatory properties, resulting in protection against autoimmunity and prolongation of allograft survival [136,156,157]. Some of the most promising analogs, coming from different chemical laboratories, have been tested in the NOD mouse [156,158] as well as in the BB rat [159]. Also in humans, the use of analogs in T1D is promising as a small clinical trial with alfacalcidol (0.25  $\mu\text{g}$  twice daily) treatment in newly diagnosed children showed preservation of beta cell function [160]. The mechanism of protection against insulinitis and diabetes appears to be similar to that of mother compound  $1,25(\text{OH})_2\text{D}_3$ . Exposure to vitamin D analogs enhances both chemotactic and phagocytotic capacity of monocytes/macrophages, while their antigen-presenting cell function decreases [161]. In DCs, analogs have an effect on cell morphology, cell surface marker, and cytokine expression (e.g., MHC-II, CD80, CD86, IL-12, and IL-10), and endocytic and migratory capacity. Hereby,  $1,25(\text{OH})_2\text{D}_3$  analogs significantly alter the antigen-presenting function of DC [172] both in vitro and in vivo, resulting in suppression of T cell activation [8,162–164]. Moreover, effects of analogs on the induction of Tregs [90,132,133], the redirection of T cells to sites of inflammation [132], and beta cell protection have been described [8,165]. In the search for the optimal analog, a combination of beta cell protection, immune modulation, and low calcemic effects is desirable.

## 9. Vitamin D in combination therapy to prevent or arrest type 1 diabetes

The hope that T1D would one day be cured by one drug or intervention is long forgotten. T1D is always described as being one entity as the clinical endpoint of insulin deficiency, requiring lifelong exogenous insulin substitution, remains the same. However, T1D is actually a collective term for a heterogeneous disease [166]. Secondly, as described before, the true culprit of disease initiation, either the pancreatic beta cell and/or an aberrant immune system, remains to be determined [166]. These observations make us realize that the solution might lay in combination therapy.

In animal models of T1D, disease prevention can be achieved by the chronic use of a myriad of different drugs such as  $1,25(\text{OH})_2\text{D}_3$ , azathioprine, cyclosporine, tacrolimus, nicotinamide, and anti-CD3, whereas disease intervention is only (partially) possible by some of these agents, such as anti-CD3 [167]. The development

of drugs that are highly selective and yet produce minimal toxicity to the host remains one of the most complicated challenges in (autoimmune) disease protection. Moreover, because the majority of diseases are treated with drugs in combination regimens rather than single agents, one practical approach to circumvent toxicity is to develop combination regimens that will potentiate the effectiveness of current (clinical) protocols without its toxicity. This strategy would accelerate the acceptance of new drugs as adjunct strategies because these molecules could be used at concentrations well below their maximal tolerable doses. For example, azathioprine can cause pancreatitis and bone marrow suppression, which may increase the risk of infection or serious bleeding [168]. Common adverse effects of calcineurin inhibitors such as cyclosporine and tacrolimus are bowel disturbance, nephrotoxicity, neurotoxicity, and serious side effects on pancreatic beta cell function such as a reduced insulin synthesis and beta cell toxicity [169,170]. Several combinations of vitamin D analogs with other immune modulators have been tested both in vitro and in vivo. Five candidates have been tested for a combination therapy with  $1,25(\text{OH})_2\text{D}_3$  (cyclosporine, tacrolimus, rapamycin, leflunomide, and mycophenolate mofetil [MMF]) and showed maximum synergism with cyclosporine [171,172]. Other immunomodulators such as type I IFNs that exhibit a broader range of immunomodulatory properties (mainly restriction of T cell proliferation and IFN- $\gamma$  production in part by inhibiting DC-mediated IL-12 secretion while promoting IL-10 production) also gave interesting results in combination with less hypercalcemic vitamin D analogs in experimental models of multiple sclerosis and T1D [173,174].

In NOD mice, diabetes can be prevented by vitamin D metabolites and analogs when treatment is started before insulinitis is present [156]. A critical question for the applicability of these analogs in the human situation is, if the vitamin D analogs can arrest progression to overt diabetes, which is the situation in prediabetic subjects in whom immune intervention is considered. Castells et al. demonstrated that some of these analogs when combined with a short induction course of cyclosporine can arrest the progression of the disease when administered after autoimmunity has already started [175]. The mechanism of protection in our model was clearly neither a generalized immune suppression nor the induction of different immune cell subsets, and cotransfer experiments with splenocytes from animals treated with the combination therapy did not reveal the presence of suppressor cells. Signs of local immunoregulation were, however, prominent locally in the islets. The approach of utilizing vitamin D analogs at concentrations that produce limited hypercalcemia, as adjuncts to conventional immunotherapy, is very

promising and might open new perspectives in the protection against T1D in humans.

In comparison with other immunosuppressive agents, vitamin D is an appealing addition in combination with antigen-based therapy due to its unique profile. Most immunosuppressive agents target T cells, or some, such as MMF, both T and B cells. Conversely, no immunomodulatory agent in clinical use specifically targets antigen-presenting cells and in particular DCs, which are known to be involved in T cell activation and tolerance induction. Vitamin D, however, is able to inhibit DC differentiation and maturation into APCs, therefore rendering DCs more tolerogenic [138–144]. The importance of these tolerogenic DCs generated from monocytes by a combined treatment with vitamin D and antigen-specific therapy is that they induce antigen-specific Tregs [176]. This feature is being exploited in antigen-based immunotherapy. Roep et al. demonstrated that proinsulin loaded vitamin D<sub>3</sub>-treated and dexamethasone-treated tolerogenic DCs in humans are safe [177]. Although further trials are needed, the first results suggest a delay or halt of the beta cell destruction. To improve efficacy of subcutaneous injections with glutamic acid decarboxylase (GAD) together with aluminum hydroxide (alum) as carrier, also Ludvigsson et al. decided to add 2000 IU/day vitamin D<sub>3</sub> to the treatment regimen [178]. Here, the addition of vitamin D<sub>3</sub> resulted in a tendency to a less rapid decline of C-peptide from 6 to 30 months with increasing serum 25(OH)D<sub>3</sub> levels being positively correlated with C-peptide preservation [178]. These trials are well underway as Ludvigsson et al. decided in a follow-up trial to change the mode of injection to intralymphatic administrations of GAD-alum, again together with 2000 IU/d vitamin D<sub>3</sub> supplementation [179]. The addition of vitamin D was again hypothesized to improve the efficacy of the treatment by its effect on the immune system [180]. In this trial, the preservation of C-peptide was only seen in patients carrying HLA DR3-DQ2 [179]. This was later confirmed in a follow-up trial specifically in T1D patients with HLA DR3-DQ2 compared with random T1D patients [181]. Based on 25(OH)D<sub>3</sub> levels, it seemed unlikely that the observed efficacy was conferred by the vitamin D supplementation [179]. This tolerogenic influence on DCs by vitamin D is also being exploited in specific bioengineering approaches to safely deliver effective antigen-based vaccines to intervene in T1D. A combination microparticle system has been established, with encapsulated vitamin D<sub>3</sub>, TGF-β1, GM-CSF, and the insulin B(9–23) peptide, which is able to modulate DC phenotype in vivo. Two subcutaneous injections with these particles could reduce diabetes incidence and insulinitis in female NOD mice, while Treg frequency increased [182,183].

Lastly, vitamin D is being exploited in combination with islet or stem cell transplantation in T1D. In T1D, the insulin-producing beta cells in pancreatic islets are destroyed by autoreactive T cells. The long-lasting persistence of autoreactive T cells in human blood and the memory phenotype displayed by at least some of these immune cells suggest the existence of an autoimmune memory [184]. The latter phenomenon is responsible for the destruction of MHC-matched or syngeneic beta cells, transplanted under the form of isolated beta cells, islets, or whole pancreas [185]. Successful transplantation requires the prevention of allograft rejection and the break of the autoimmune memory. Some analogs of 1,25(OH)<sub>2</sub>D<sub>3</sub> have been tested for their capacity to prevent disease recurrence after islet transplantation in spontaneously diabetic NOD mice. The most spectacular results were obtained with a combination of KH1060 (20-epi-22-oxa-24,26,27-trishomo-1,25(OH)<sub>2</sub>D<sub>3</sub>) and subtherapeutic doses of cyclosporine [186]. In the group receiving KH1060 (0.5 µg/kg/2 days) together with cyclosporine (7.5 mg/kg/day), a synergistic effect between both drugs was observed: four out of seven mice maintained a functioning graft for 60 days and did not show recurrence for at least 30 days after stopping the treatment. Treatment was administered from the day before transplantation until diabetes recurrence or in case of persistent normoglycemia until 60 days after transplantation. The subtherapeutic doses of KH1060 together with cyclosporine were nontoxic and had minor effects on serum calcium levels, although osteocalcin levels were clearly elevated, and bone calcium content was decreased. In addition, 1,25(OH)<sub>2</sub>D<sub>3</sub> improved islet graft survival time in diabetic rats through inhibition of nonspecific inflammation [187]. Another approach can be found in combinations of vitamin D analogs and other natural immune modulators. For example, subtherapeutic doses of recombinant (r) IFN-β alone (1 × 10<sup>5</sup> IU/day) had minor effects on autoimmune diabetes recurrence after islet transplantation (20.8 ± 14.2 days vs. 10.8 ± 2.9 days in controls). However, interestingly, a combination of rIFN-β with TX527 (14-epi-19-nor-20-epi-23-yne-1,25(OH)<sub>2</sub>D<sub>3</sub>) maintained islet graft function in 100% of mice during treatment and resulted in a marked delay of autoimmune diabetes recurrence (61.6 ± 19.6 days) [174]. Moreover, the combination of rIFN-β with TX527 resulted in an inhibition of the Th1 pathway (IL-12, IL-2, and IFN-γ), which is known to be associated with the pathogenesis of organ-specific autoimmune diseases. In addition, enhanced expression of the regulatory cytokine, IL-10, by rIFN-β and TX527 therapy, was observed. A study by Baeke et al. reported that combining low doses of anti-CD3, TX527, and cyclosporine can protect NOD mice from diabetes recurrence after syngeneic islet

**FIGURE 100.3** The pathogenesis of T1D is a complex interplay of genetic predisposition, the pancreatic beta cell, and the immune system, resulting in the autoimmune destruction of the insulin-producing beta cell. Vitamin D and its metabolite  $1,25(\text{OH})_2\text{D}_3$  have the ability to intervene at all three levels, thereby affecting disease onset and progression. Genetic polymorphisms in vitamin D–related genes (e.g., VDR, DBP,  $1\alpha$ -OHase (CYP27B1)) and  $24\text{-OHase}$  (CYP24A1) have been shown to associate with an increased diabetes risk. In addition, vitamin D deficiency due to a lack of sunlight exposure, low vitamin D dietary intake, or a defect in vitamin D–metabolizing enzymes is a risk factor influencing disease onset. In this context, vitamin D supplementation during the first year of life could reduce T1D in NOD mice and humans. The presence of the VDR in the pancreatic beta cells, the expression of  $1\alpha$ -hydroxylase in pancreatic beta cells, and the presence of a vitamin D response element in the human insulin receptor gene promoter indicate that vitamin D has an influence on the beta cell. Indeed, beta cell function is improved by  $1,25(\text{OH})_2\text{D}_3$  as it protects against ER-induced beta cell stress. Vitamin D almost completely prevents beta cell death induced by inflammatory cytokines  $\text{IL-1}\beta$  and  $\text{IFN-}\gamma$  as it makes them less visible for the immune system and reduces the attraction signals for the immune system secreted by beta cells themselves. Furthermore, vitamin D induces the expression of antiapoptotic A20 protein. The presence of the VDR as well as vitamin D–metabolizing enzymes in several cells from the immune system was a first indication for the immunomodulatory effects of  $1,25(\text{OH})_2\text{D}_3$ . In macrophages,  $1,25(\text{OH})_2\text{D}_3$  increases the chemotactic and phagocytic capacity together with enhanced antimicrobial properties. In addition,  $1,25(\text{OH})_2\text{D}_3$  induces a shift from Th1 and Th17 toward a Th2 T cell response. Moreover, T cell behavior is also indirectly regulated by  $1,25(\text{OH})_2\text{D}_3$  through modulation of dendritic cell (DC) phenotype. Here,  $1,25(\text{OH})_2\text{D}_3$  is able to reshape DCs toward tolerogenic cells with reduced expression of antigen-presenting and costimulatory molecules as well as proinflammatory cytokines, subsequently affecting its T cell stimulatory capacity resulting in T cell anergy and induction of antigen-specific Tregs. As a result of the multilevel impact of vitamin D, this molecule could have a contributing role for the prevention or treatment of T1D; however, solid clinical data is currently lacking.

transplantation [188]. Remarkably, mice receiving all three drugs survived longer ( $69 \pm 10$  days) than mice receiving one or two agents and remained normoglycemic during the whole treatment period. Combining

these drugs enhances their individual potency but also offers an interesting strategy to circumvent dose-related side effects of immunosuppressants currently used in clinical transplantation.

More recently, stem cell transplantation has emerged as a potential treatment for T1D due to its intrinsic regenerative capacity and immunomodulatory properties, which may arrest the autoimmune beta cell destruction and generate functional beta cells [189]. Allogenic adipose tissue–derived stromal/stem cells are tested together with vitamin D as immunosuppressant in patients with recent onset T1D [190]. This resulted in stability of C-peptide, better glucose control, and lower insulin requirements compared with controls. A larger prospective open trial is currently ongoing ([ClinicalTrials.gov](https://clinicaltrials.gov) no. NCT03920397).

## 10. Conclusion

Since the discovery that sunlight affects the onset of T1D with increased incidence rates in the winter months and in regions further away from the equator, the relation between vitamin D and T1D has been indisputable. Whereas the initial hypothesis was that vitamin D deficiency would be an environmental factor that could potentially trigger the onset of T1D, extensive research in the past four decades demonstrated an indisputable relation between vitamin D and all the different players in the pathogenesis of T1D. Both in vitro and in vivo trials in both animal models and humans demonstrated that the key aspect of vitamin D is in the prevention of T1D. This is achieved by interacting with both the beta cells and the immune system (Fig. 100.3). Recent research demonstrates an even more complex and elaborate association. In particular, T1D starts in a genetically at-risk individual where polymorphisms of the *VDR*, the vitamin D-metabolizing enzymes *CYP27B1* and *CYP24A1*, or the *DBP* gene can influence the risk of T1D. Besides its crucial role in the prevention of T1D, the immunomodulatory effects of vitamin D have been explored in the stabilization of the beta cell destruction in T1D. Here, just as for other immunomodulators, clinical trials have mostly failed. An important reason might be that the choice of the vitamin D metabolite and its dose and frequency of administrations are critical factors that need to be considered when designing clinical trials. To achieve a higher dosing regimen without eliciting toxic side effects, vitamin D analogs have been designed with mixed results. Lastly, the hope that T1D could ever be prevented by one drug or intervention is long forgotten. However, due to its unique characteristics, vitamin D is an appealing add-on in combination regimens, already showing promising results.

At present, the only solid conclusion from the data on vitamin D and T1D is that vitamin D deficiency should be avoided at all cost. Long-term intervention studies are needed to demonstrate if vitamin D plays a crucial

role in the rising incidence of T1D and how and when supplementing individuals can prevent or arrest T1D.

## 11. Summary points

- There is a clear association between vitamin D deficiency and type 1 diabetes.
- Vitamin D and its analogs are able to protect the beta cell and drive the immune system toward immune tolerance.
- In animal models of T1D, high doses of vitamin D metabolites and analogs prevent type 1 diabetes.
- In humans, the role of vitamin D in preventing or arresting type 1 diabetes is unclear.
- Due to its unique immune characteristics, vitamin D is an appealing add-on in combination regimens in future trials to prevent or arrest type 1 diabetes.

# Vitamin D mechanisms of protection in multiple sclerosis

Colleen E. Hayes<sup>1</sup>, Anne L. Astier<sup>2,a</sup> and Matthew R. Lincoln<sup>3,a</sup>

<sup>1</sup>Department of Biochemistry, University of Wisconsin-Madison, Madison, WI, United States <sup>2</sup>Toulouse Institute for Infectious and Inflammatory Diseases Research, INSERM U1291, CNRS UMR5051, Université Toulouse III, Toulouse, France <sup>3</sup>Division of Neurology, St. Michael's Hospital and Keenan Research Centre for Biomedical Science, University of Toronto, Toronto, ON, Canada

## OBJECTIVES

- Present foundational information on MS pathogenesis and sexual dimorphisms that characterize this autoimmune demyelinating disease.
- Review current knowledge gleaned from Mendelian randomization studies that now confirm vitamin D insufficiency as a cause for MS, and clarify how the vitamin D hormone and the nuclear VDR are likely to directly and indirectly influence MS-relevant gene expression at every step in the transcriptional process and in many types of cells.
- Explain how the MS sexual dimorphism data implicate participation of the vitamin D hormone and the nuclear VDR in a CD4<sup>+</sup> T cell intrinsic mechanism that is regulated by the sex hormones, estradiol and testosterone, and suggest a hypothetical model for hormonal regulation of the *FOXP3* gene that may explain the MS sexual dimorphism data.
- Clarify how the proinflammatory, IFN $\gamma$ -producing CD4<sup>+</sup> Th1 cells direct the immune response to pathogens, how the antiinflammatory, IL-10-producing CD4<sup>+</sup> Tr1 cells protect tissues from immune-mediated damage, and how the

vitamin D hormone and the nuclear VDR serve as a highly localized signal to drive CD4<sup>+</sup> Th1 cells to transdifferentiate into protective CD4<sup>+</sup> Tr1 cells when a pathogen has been cleared.

- Describe the importance of oligodendrocytes and the myelin sheath to proper brain function, summarize evidence that the vitamin D hormone and the nuclear VDR provide signals that promote oligodendrocyte precursor cell differentiation into myelinating oligodendrocytes, and suggest a hypothetical model for VDR regulation of the methionine cycle and epigenetic silencing of repressive genes whose function is to maintain oligodendrocyte precursor cells in an immature state.
- Suggest research challenges from the vitamin D and MS perspective to discover MS-relevant genes that are differentially expressed in the vitamin D—replete and vitamin D—deficient states and elucidate the transcriptional control mechanisms; to probe the biochemistry of vitamin D hormone synthesis in the context of inflammation and evaluate the relationship between vitamin D status and methionine cycle function; to define how the vitamin D system impacts regulatory T cells of all types and their immune checkpoints; to investigate the

<sup>a</sup> These authors contributed equally to the review.

connections between nutrition, methionine cycle function, and MS; and finally, to conduct additional robust and thoughtfully designed vitamin D<sub>3</sub> intervention trials, with longitudinal measurement of biomarkers and clinical data, in an effort to find accessible indicators of a prodromal period for MS disease when a vitamin D<sub>3</sub> intervention might alter the trajectory toward an MS diagnosis.

## 1. Introduction

The first probable case of multiple sclerosis (MS), an autoimmune demyelinating disease of the central nervous system (CNS), was described in a letter written in 1757 by Patrick Brydone to Scottish physician Robert Whytt [1]. At that time, Brydone's use of "upward of 600 severe shocks" as a therapeutic trial elicited published comment from Benjamin Franklin, who had also attempted electric shock therapy in paralytic patients. Now, 265 years later, MS afflicts ~2.8 million people worldwide, with a new case being diagnosed in an adult at a highly productive stage of life about every 5 min [2]. The global MS disease burden nearly tripled in the half-century before 2013 [3,4] and has nearly doubled since then [2]. Neurological deficits gradually deprive MS patients of movement, sensory perception, cognition, emotional well-being, independence, and livelihood. Despite decades if not centuries of research and an arsenal of approved medications, MS remains incurable.

Multiple sclerosis is so named for its signature pathological features: focal demyelinating lesions disseminating in time and space [5]. The earliest focal lesions surrounding the perivascularity exhibit myelin instability and fragmentation, phagocytosis of fragments by myelin-laden macrophages, loss of myelinating capacity by oligodendrocytes (OLG), activated microglia, T cells (T lymphocytes), reactive astrocytes, and axonal loss. The focal nature of early lesions suggests that demyelination may result from a highly localized inflammatory response and possible oxidative damage to the myelin rendering it unstable and easily fragmented. The chronic lesions that develop later in the disease process share many features with the early lesions. In addition, slowly expanding lesions may be seen with smoldering, chronic inflammation, and tissue sclerosis. The neurological deficits that characterize MS are attributed to chronically demyelinated axons, consequent transmission failure, axonal degeneration, and finally, neuronal cell death.

When this chapter was last updated, deep skepticism greeted several aspects of the vitamin D-MS hypothesis [6]. Scientists debated whether the protective

association between sunlight exposure and lower risk of MS reflected cutaneous vitamin D<sub>3</sub> synthesis and the biological actions of the vitamin D hormone, 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>), and its vitamin D receptor (VDR). Moreover, disbelief confronted emerging data showing that relapsing-remitting MS (RRMS) incidence and prevalence had tripled in just a few decades in a female-biased manner [7]. The global scope, magnitude, and rapidity of this female-biased increase implied that it had nongenetic etiological roots. The hypothesis that the globally declining population vitamin D status might be contributing to the rapidly increasing MS incidence had not taken hold [8]. Controversy persisted concerning the proposal that extrarenal 1,25(OH)<sub>2</sub>D<sub>3</sub> synthesis and autocrine and paracrine signaling within and between the immune system and the brain might influence MS risk, since these mechanisms had not been demonstrated in vivo [9]. The 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated transcriptional control of many MS-relevant genes had been demonstrated in T lymphocytes and monocytes, but how such control was sometimes asserted in the absence of defined vitamin D-responsive elements (VDREs) remained enigmatic [10].

Here, we summarize the remarkable recent advances that have deepened our understanding of the vitamin D system's protective mechanisms and strengthened the inference that vitamin D insufficiency contributes causally to MS pathogenesis, consistent with the Bradford-Hill paradigm [11]. New genetic studies have highlighted the role of epigenetic mechanisms as integration points for gene-environment interactions in MS [12]. Recent Mendelian randomization studies (reviewed in the following and in Chapter 61), and animal modeling experiments [13], have left no doubt that 25-hydroxyvitamin D<sub>3</sub> (25(OH)D) and the capacity of immune cells to produce and use 1,25(OH)<sub>2</sub>D<sub>3</sub> for autocrine and paracrine signaling strongly influence MS disease risk and severity. New immunological studies have provided more precise mechanistic details concerning the proposed CD4<sup>+</sup> T lymphocyte transdifferentiation model, wherein the presence or absence of pathogens determines highly localized 1,25(OH)<sub>2</sub>D<sub>3</sub> production and subsequent switching of proinflammatory CD4<sup>+</sup> T helper type-17 (Th17) cells into CD4<sup>+</sup>FOXP3<sup>+</sup> T regulatory (Treg) cells, as well as switching of proinflammatory CD4<sup>+</sup> T helper type-1 (Th1) cells into antiinflammatory CD4<sup>+</sup> T regulatory type-1 (Tr1) cells through the complement receptor (CD46) [14] (see Chapter 96).

Our understanding of mechanisms by which 1,25(OH)<sub>2</sub>D<sub>3</sub> and VDR assert transcriptional control over MS-relevant genes has also deepened. Important details have emerged concerning mechanisms of 1,25(OH)<sub>2</sub>D<sub>3</sub> and VDR transcriptional control of the *Foxp3*, *Ikzf2*, and *Ctla4* genes in CD4<sup>+</sup>FOXP3<sup>+</sup> Treg cells.

Other recent biochemical data have demonstrated 1,25(OH)<sub>2</sub>D<sub>3</sub> and VDR transcriptional control of betaine–homocysteine methyltransferase (BHMT), the methionine (MET) cycle, and DNA-methylation in CD4<sup>+</sup> T lymphocytes [15]. The MET cycle is dysregulated in MS patients [16]. Recent research localized BHMT to the oligodendrocyte nucleus where it was bound to DNA-methyltransferase-3a (DNMT3a) [17]. Enhanced methyl donor availability in the nucleus promoted epigenetic DNA and histone methylation changes that stimulated oligodendrocyte precursor cell (OPC) maturation to a myelinating phenotype.

In this chapter, we integrate the many remarkable advances to describe how extrarenal 1,25(OH)<sub>2</sub>D<sub>3</sub> synthesis and autocrine and paracrine signaling to VDR-expressing cells (see Chapter 9) determine the differentiation and function of CNS cells and immune system cells. Some mechanisms involve direct gene regulation through ligand-activated VDR interactions with gene promoters, enhancers, and other transcriptional factors. Other mechanisms require stimulation of the MET cycle to provide single carbon units for epigenetic control of cell differentiation and function. These mechanisms are exquisitely sensitive to the female sex hormone, estradiol (E2), and to the presence of pathogens. We close the chapter with a summary of the many remarkable advances, and a perspective on questions raised but not yet answered. We hope this review will stimulate new research into vitamin D mechanisms of protection in MS with the dual goals of reversing the troubling female-biased trend of increasing MS incidence and prevalence and preventing MS or reducing the impact of MS for individuals with this diagnosis.

## 2. Vitamin D and MS genetics

### 2.1 Early genetic support for vitamin D insufficiency in MS pathogenesis

A role for vitamin D insufficiency in MS pathogenesis was first suggested by the striking inverse correlation between birth latitude and MS risk in a cohort of US veterans [18], with MS being more prevalent in northern counties. Though similar MS prevalence gradients had been reported previously [19,20], this study used place of birth to control for migration and highlighted the inverse correlation with solar radiation, particularly in winter months. Latitudinal risk gradients are now confirmed in diverse populations and correlate strongly with ultraviolet radiation exposure [21] (see Chapter 102).

Migration studies suggested that MS risk associated with higher latitudes was established in early life. Risk of MS among migrants from the United Kingdom to

South Africa was reduced when migration occurred before 15–16 years of age [22]. Conversely, South Asian migrants to the United Kingdom had higher MS risk if they migrated before 15 years of age than if they migrated later [23]. Similar age-dependent alterations in MS risk have been observed in several migrant populations [24–27]. Childhood outdoor leisure activities and sun exposure were associated with lower MS risk [28–31], further supporting a role for vitamin D in early life.

A month-of-birth effect, observed in several high-latitude MS cohorts [32], provided further evidence for a seasonal risk factor. An excess of MS patients born in May following a period of relative maternal vitamin D insufficiency, together with fewer born in November, suggested that a seasonal risk factor may act in utero or in the immediate postpartum period, possibly through vitamin D–insufficient breast milk. While such studies may be confounded by year or place of birth [33], consistent observation in independent populations [34] lends credence to a seasonal factor operative in early life.

The vitamin D–MS hypothesis is highly favored to explain these observations [35], but they could in principle reflect another, as yet undefined environmental factor that varies with latitude, season, and/or sunlight exposure. Several genetic approaches have been used to test the vitamin D–MS hypothesis. In the first of these, vitamin D metabolism-related candidate genes were investigated [36]; if vitamin D insufficiency is the causal factor responsible for latitudinal gradients and seasonal effects, then genetic variation in vitamin D metabolism–related genes would be expected to influence MS risk. Early candidate gene studies provided variable support for variants near *VDR* [37–39], *CYP27B1* [36,40], and *MC1R* [39]. These early studies were underpowered, did not employ modern quality control techniques, and did not address population stratification. It is not surprising, then, that reported associations were frequently refuted in larger cohorts [36,41–44].

The advent of genome-wide association study (GWAS) methods permitted more definitive investigation of vitamin D pathways. Genes involved in vitamin D metabolism have been associated with MS in multiple studies. The *CYP24A1* gene encoding the 1,25-dihydroxyvitamin D<sub>3</sub> 24-hydroxylase (24-hydroxylase) that inactivates 1,25(OH)<sub>2</sub>D<sub>3</sub> has been consistently highlighted in several large GWAS of MS [45–47]. The *CYP27B1* gene encoding the rate-limiting enzyme for 1,25(OH)<sub>2</sub>D<sub>3</sub> biosynthesis, 25-hydroxyvitamin D 1 $\alpha$ -hydroxylase (1 $\alpha$ -hydroxylase), was highlighted in an early GWAS [48], replicated in an independent cohort [49] and again in meta-analysis [45]. The *CYP27B1* gene that encodes 1 $\alpha$ -hydroxylase emerged as a leading functional

candidate because this enzyme converts 25(OH)D<sub>3</sub> to active 1,25(OH)<sub>2</sub>D<sub>3</sub>. Although *CYP27B1* was an appealing functional candidate, the association lay in a gene-dense region. A subsequent fine-mapping study favored nearby *TSM* [46], whereas the most recent GWAS and meta-analysis favored *OS9* [47]. These discrepancies illustrate a major challenge in GWAS interpretation; translation of association signal to functional mechanism is difficult, and ranking genes by proximity to the lead variant is unreliable. Functional validation of GWAS results is essential, particularly in pathologically relevant tissues and environmental contexts.

Because GWAS are powered to detect common variation, they can miss rare variants (i.e., present at <1% frequency) that may have large individual effects on disease risk. Rare loss-of-function variants in *CYP27B1* may provide an example of this phenomenon. In homozygous form, several of these variants cause vitamin D hydroxylation-deficient rickets type 1A (VDDR1A; OMIM 264700) (see Chapter 66). Reasoning that VDDR1A might be a risk factor for MS, Norwegian investigators found three rare patients from two families with a co-occurrence of VDDR1A and MS, who were diagnosed with VDDR1 as children and later developed MS [50]. Applying whole-exome sequencing to a collection of multiplex MS families, investigators found suggestive association with a coding variant R389H previously known to cause VDDR1A in homozygous form [51]. This allele was not detected in a more recent, larger, international case-control study of low-frequency variants [52]. These complexities demonstrate the importance of study design and the inherent challenge of studying rare variants.

Taken together, genetic association studies provide important clues that vitamin D metabolism may influence MS risk, but these studies must be interpreted with caution. While GWAS can rigorously demonstrate association, translation of these associations into functional mechanisms is a challenging, and largely unsolved, problem.

## 2.2 Mendelian randomization studies establish vitamin D insufficiency as causal for MS

Observational epidemiology provided several lines of evidence for an inverse association between serum 25(OH)D levels and MS risk (see Chapter 102). Causal inference from observational studies is challenging: associations may be confounded by unknown or unmeasured environmental factors, measurement of potential risk factors is subject to recall bias, and risk factors may also be influenced by the disease, which is termed reverse causation. It is difficult, therefore, to translate associations between latitude or vitamin D status and MS

disease into causal statements based on observational techniques alone.

Mendelian randomization studies have been used to circumvent these issues and probe the causal relationship between low serum 25(OH)D and MS with greater certainty (see Chapter 61). In Mendelian randomization, genetic variants that determine a potentially causal factor, for example, low serum 25(OH)D levels, are identified (e.g., through GWAS, Chapter 60). The genetic variants are then used as a proxy for the factor and tested for association with a phenotype like MS, subject to a limited set of assumptions [53]. The genetic variants being used as a proxy are randomized at meiosis, whereas the disease of interest, MS, develops later in life. Thus, this causal inference framework is akin to a randomized controlled trial. Importantly, Mendelian randomization studies minimize reverse causation that has plagued other designs. In other words, the development of MS in adulthood does not alter the genetic variants that drive serum 25(OH)D levels. Consequently, Mendelian randomization studies now provide evidence of a causal relationship between the factor, low serum 25(OH)D levels, and the phenotype, MS. However, lifelong exposure to vitamin D insufficiency alone is not enough to cause MS disease; other genetic, environmental, and hormonal factors also play a role.

Genome-wide association [54–58] and whole-genome sequencing [59] studies have defined genetic factors that influence serum 25(OH)D levels (see Chapter 60). The initial SUNLIGHT GWAS identified three single-nucleotide polymorphisms (SNPs), rs6013897, rs10741657, and rs12785878, which were linked to three vitamin D metabolism genes, *CYP24A1*, *CYP2R1*, and *DHCR7*, respectively, all of which were independently associated with lower serum 25(OH)D levels [54]. There are now 143 independent SNPs that have been independently associated with serum 25(OH)D levels [58].

Using the three SNPs from the initial SUNLIGHT GWAS, Mendelian randomization demonstrated that low serum 25(OH)D level is a causal influence in both adult [60,61] and pediatric [62] MS risk. In all three studies, risk of MS increased with decreasing, genetically predicted serum 25(OH)D levels. These observations have since been replicated using larger GWASs [63]. It is important to recognize that the genetic factors employed in Mendelian randomization are present throughout the life of the individual, and thus may not adequately model vitamin D status specific to a critical period (e.g., adolescence). This minor limitation aside, genetic studies now provide strong evidence for vitamin D insufficiency as a causal influence in MS.

Mendelian randomization may also be used to disentangle multiple correlated traits. Obesity has been causally linked to MS by Mendelian randomization [64]. Since obesity may lower the bioavailability of fat-

soluble 25(OH)D<sub>3</sub>, obesity had been hypothesized to act by influencing bioavailability of vitamin D<sub>3</sub> and 25(OH)D<sub>3</sub> [65]. Using Mendelian randomization mediation analysis, both vitamin D and obesity were shown to be independently causal, with only 5.2% of the body mass index causal effect attributed to the secondary lowering of 25(OH)D<sub>3</sub> [66]. This is consistent with prior studies that did not model mediation effects but showed the causal effect of genetically determined 25(OH)D<sub>3</sub> levels to be independent of childhood body mass index [62,67].

### 2.3 Vitamin D provides epigenetic insights into MS pathogenesis

As in other autoimmune diseases, the genetic variants that drive MS risk are almost exclusively noncoding and enriched in open chromatin regions that are active in immune cells [68–70]. As a class, causal variants act by disrupting gene regulatory elements and altering gene expression. Identification of the downstream transcriptional mechanisms that transduce MS risk remains incomplete, with a minority of loci tied definitively to transcriptional targets [71]. This *variant-to-function problem* remains a major focus of the international MS genetics community. To define molecular mechanisms relevant to MS pathogenesis, we must identify, for each GWAS locus, (1) the relevant regulatory element that is disrupted, (2) the transcription factor whose binding is perturbed, (3) the gene(s) that are transcriptionally regulated, and (4) any relevant downstream molecular pathways. Epigenetic mechanisms such as histone modification and DNA methylation [72] are likely important mechanisms. A recent GWAS showed that 19 MS-associated SNPs were also associated with DNA methylation quantitative trait loci in MS patient CD4<sup>+</sup> T cells [73], providing possible insight into their mechanisms of action. To identify these downstream mechanisms for all MS loci is an enormous task, especially since chromatin accessibility, transcription factor binding, and other epigenetic mechanisms vary in different cell types and environmental conditions. We must therefore also specify the relevant cell type, and conditions under which dysregulation occurs.

The vitamin D system transduces signals derived from cutaneous exposure to the sun's ultraviolet radiation into a biologically active hormone, 1,25(OH)<sub>2</sub>D<sub>3</sub> (also termed calcitriol), that ultimately plays important roles at several points in transcriptional control of gene expression. After ingestion or production in the skin, vitamin D<sub>3</sub> is hydroxylated in the liver to 25(OH)D<sub>3</sub>, the most abundant circulating vitamin D metabolite and the best biomarker of vitamin D status. The second hydroxylation reaction is catalyzed by the 1 $\alpha$ -hydroxylase that is encoded by the *CYP27B1* gene discussed

before (see Chapters 4, 8, and 9). In the kidney and some extrarenal tissues [74], the 1 $\alpha$ -hydroxylase produces 1,25(OH)<sub>2</sub>D<sub>3</sub> (see Chapters 8 and 9). The 1,25(OH)<sub>2</sub>D<sub>3</sub> then binds to the VDR-retinoid X receptor heterodimer. This ligand-activated heterodimer binds to genomic VDREs where it influences transcription of a diverse array of genes (see Chapters 10–12).

The specific transcriptional relevance of the liganded VDR in MS was suggested by discovery of a putative VDRE in the promoter region of the *HLA-DRB* gene [75]. Excluding the rare loss-of-function *CYP27B1* mutations mentioned before, *HLA-DRB1\*1501* is the strongest genetic determinant of MS risk, with an odds ratio between 2 and 3 [76]. The putative VDRE sequence was most strongly conserved on *HLA-DRB1\*15* haplotypes, varying on other human leukocyte antigen (HLA) haplotypes with diverse effects on MS risk. In transfection experiments using lymphoblastoid cell lines, *HLA-DRB1* expression was induced upon stimulation with 1,25(OH)<sub>2</sub>D<sub>3</sub>. However, appropriate biochemical experiments such as systematic mutational analyses, VDR-RXR binding experiments, and promoter activation studies were not performed to test the function of this putative VDRE sequence in vitro or in vivo in primary B cells (see Chapter 13). Although the B lymphoblastoid cell line studies focused attention on a critical MS risk allele, they have not yet provided biochemical evidence that 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling enhances its expression by means of a VDRE.

Outside the HLA region, VDREs have been mapped genome-wide using the chromatin immunoprecipitation and sequencing (ChIP-seq) method. In this technique, cellular DNA is cross-linked to bound proteins, sheared into short fragments, and then immunoprecipitated using antibodies against a protein of interest (e.g., VDR). Sequencing of DNA fragments bound to the protein of interest provides a genome-wide distribution of its binding sites. Initial studies investigated VDR binding in B lymphoblastoid cell lines [77] or the THP-1 monocytic leukemia cell line [78,79], both before and after treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub>. VDR binding increased dramatically in both systems after 1,25(OH)<sub>2</sub>D<sub>3</sub> stimulation. In B lymphoblastoid cell lines, the VDR bound to 623 sites at baseline, increasing to 2776 after 36 h of stimulation [77]. The VDR bound to several MS-associated loci discovered by GWAS, including *IRF8* and *PTPN2*. In THP-1 monocytic leukemia cells, 1820 VDR-binding sites were identified after 40 min of stimulation [78], with 11,657 reaching nominal significance over a 24 h time course [79]. Both studies identified numerous genes differentially expressed upon 1,25(OH)<sub>2</sub>D<sub>3</sub> stimulation [77,79,80], with many of these associated with transient or persistent VDR binding [80] (see Chapters 12 and 13).

Disease-relevant transcriptional targets of the ligand-activated VDR are best identified in disease-relevant

cells, because chromatin accessibility and transcription factor binding vary across cell types. Following the demonstration that  $1,25(\text{OH})_2\text{D}_3$  action directly on the VDR in  $\text{CD4}^+$  T lymphocytes was necessary and sufficient for experimental autoimmune encephalomyelitis (EAE) inhibition in rodents [81], investigators mapped the ligand-activated VDR binding sites in primary human  $\text{CD4}^+$  T cells using the ChIP-seq method [82]. The number of VDR-bound sites in the  $\text{CD4}^+$  T cell DNA increased with the serum  $25(\text{OH})\text{D}$  level of the cell donor, and samples from donors with higher  $25(\text{OH})\text{D}$  levels exhibited a higher proportion of intronic binding. The VDR binding sites overlapped with previously identified ChIP-seq peaks for VDR cofactors SP1, ETS1, NR4A1, and c-MYC, with CTCF-binding sites in K562 chronic myelogenous leukemia cells, and with chromatin accessibility in  $\text{CD4}^+$  Th1 cells. The VDR binding was enriched near SNPs associated with autoimmune disease, confirming the importance of the ligand-activated VDR to the transcriptional mechanisms of autoimmune disease. These findings argue for additional, larger studies in more diverse collections of primary human immune cells.

A comprehensive DNA methylation analysis of peripheral blood monocytes from MS cases and healthy controls identified a differentially methylated region (DMR) encompassing *HLA-DRB1* exon 2, with lower overall methylation in the MS cases [83]. In homozygous carriers of the *DRB1\*1501* risk gene, this DMR was significantly hypomethylated and predominantly expressed compared with heterozygous carriers and noncarriers. Locus-specific pyrosequencing confirmed the hypomethylation status of homozygous *DRB1\*1501* carriers. Causal inference analysis and Mendelian randomization revealed a significant causal relationship between methylation at DMR3 or DMR4 and reduced *HLA-DRB1* gene expression in monocytes. Lastly, these investigators identified an MS-associated variant that was undetectable by conventional genetic analysis and appeared to protect against MS by modulating DNA methylation in *HLA-DRB1*. It will be very interesting to learn whether an individual's vitamin D status is associated with the methylation status of these DMRs in *HLA-DRB1* exon 2. In particular, it would be most interesting to examine this question in the context of monozygotic twins who are discordant for MS disease, as was done previously in a longitudinal study of monozygotic twins who were discordant for type 1 diabetes to discover a DMR that preceded disease diagnosis [84].

Since the transcriptional effects of ligand-activated VDR signaling are likely to vary in different cell types, recent studies have begun to examine discrete immune cell subsets sorted by multiparameter flow cytometry. Profiling a set of 570 immune-related genes and microRNAs in flow-sorted primary human T cells

demonstrated that the *GM-CSF* transcripts were reduced and the *IL10* transcripts were increased in the memory  $\text{CD4}^+$  T cell subset after stimulation with anti-CD3 and anti-CD28 in the presence of  $1,25(\text{OH})_2\text{D}_3$  [85]. The  $1,25(\text{OH})_2\text{D}_3$ –VDR signaling also induced immunomodulatory cytokine genes *IL10* and *IL6*, along with several miRNAs and transcription factors such as *RUNX1*. Focusing on MS-associated genes in  $\text{CD4}^+$  T cells, results showed that *IL2RA* was induced, and *TAGAP* was repressed, on in vitro treatment with  $1,25(\text{OH})_2\text{D}_3$  [86]. These studies illustrate the need for larger transcriptional studies in specific primary human immune cell subsets.

In addition to its direct influence on gene transcription, VDR signaling is likely to influence MS-relevant gene expression through a variety of indirect epigenetic mechanisms. The ligand-activated VDR appears to act as a pioneer transcription factor, opening chromatin for subsequent gene regulation either directly [80] or by recruiting other pioneer factors [87,88] (see Chapter 12). The ligand-activated VDR may alter topologically associating domains and histone modifications [89] (see Chapter 13). Thus, the ligand-activated VDR is involved at every step in the epigenetic regulation of gene expression, from chromatin opening and recruitment of pioneer factors through direct action as a transcriptional regulator.

### 3. MS sexual dimorphism

#### 3.1 Female–male differences provide insight into MS etiology

Understanding the vitamin D system's role in MS molecular etiology will require mechanistic knowledge of its contributions to the sexual dimorphisms that characterize this disease. The highly significant female–male differences in MS prevalence, incidence, disease natural history, onset age, effects of puberty, and risk gene penetrance are not understood [90–93]. Most concerning is the rising global F:M MS incidence ratio attributed to an increase in female cases [7]. Between the 1930 and 1989 birth cohorts, the composite F:M MS incidence ratio increased from 1.9 to 4.6 in high-latitude countries ( $>45$  degrees), and from 1.5 to 2.3 in low-latitude countries ( $<45$  degrees) [94]. Over the same time period, population vitamin D status has declined precipitously [7]. The latitude gradient and the coincidence of the MS and vitamin D status trends suggest a causal relationship. The consistent correlation between latitude, decreasing sunlight exposure, decreasing  $25(\text{OH})\text{D}$  levels, and increasing MS prevalence has recently strengthened [95–97]. Taken together, these observations raise the question what biochemical mechanisms

could link declining 25(OH)D status with increasing MS risk in a female-biased manner?

The correlation between increasing 25(OH)D levels, increasing CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells, and decreasing CD4<sup>+</sup> Th17 cells is a consistent observation in humans and mice, but the genetic and biochemical basis for it is unknown. The previous version of this chapter addressed this question through a detailed discussion of the synergy between 1,25(OH)<sub>2</sub>D<sub>3</sub> and 17β-estradiol (E2) in CD4<sup>+</sup> T cells that yielded more numerous CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells and fewer CD4<sup>+</sup> Th17 cells [6]. Loss of this synergy with declining 25(OH)D levels in females but not males could be a mechanism linking vitamin D status to MS risk in a female-biased manner.

In this updated chapter, we summarize and interpret MS sexual dimorphisms to derive insight into the underlying mechanism(s). The sex hormones E2 and testosterone (TST) and epigenetic control of sex chromosome-linked genes such as the human *FOXP3* and rodent *Foxp* genes are strongly implicated in these mechanisms. Accordingly, we next summarize and interpret observations concerning the impact of 1,25(OH)<sub>2</sub>D<sub>3</sub> and the sex hormones on CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells. Thereafter, we review transcriptional control of the *FOXP3* gene in some detail to derive a hypothetical model for hormonal regulation of its transcription. We close with this hypothetical model wherein the VDR, estrogen receptor-α (ERα), and androgen receptor (AR) engage with individual *FOXP3* gene enhancer regions in CD4<sup>+</sup> T cells to activate the gene promoter differently in females and males.

### 3.2 F:M incidence data over time and in transsexual individuals suggests hormone–gene interactions influence female MS risk

The most significant sexual dimorphism in MS is the threefold higher disease risk faced by women compared with men (Table 101.1). This sexual dimorphism is commonly attributed to the stronger female innate and adaptive immune response to pathogens, which is characteristic of all vertebrate species [109]. An example is the stronger female immune response to pathogen-associated molecular patterns, which has been attributed to XX versus XY chromosomal differences in the expression of a pattern recognition receptor [92]. Another example is the stronger female interferon-α response to viral infections. This sex difference has been attributed to E2 and ERα enhancement of *IFNA1* gene transcription [110]. These mechanisms are important, and there is little doubt that sex hormones and sex chromosomes contribute to them. However,

these commonly cited mechanisms rely on fixed traits, specifically, the female versus male differences in XX versus XY DNA sequences and/or sex hormones. Mechanisms based solely on fixed traits cannot explain temporal trends. The temporal trend in female MS risk calls for a mechanism that includes a corresponding temporal trend in the suspected driver. The upward temporal trend in population hypovitaminosis D incidence is the best candidate for the driver of rising female MS incidence.

Sex differences exist with respect to MS risk heritability within multiplex families. In particular, there is a strong maternal parent-of-origin effect. In half-siblings, MS recurrence risk is highest when the MS index case is the mother [111]; in aunt/uncle–niece/nephew pairs [112], risk is highest when the index case is the aunt. In a large cohort of MS multiplex families, the F:M case ratio was higher for individuals possessing the *HLA-DRB1\*15* allele than for those who were *HLA-DRB1\*15*-negative [100]. Expression of this HLA class II allele may be regulated by 1,25(OH)<sub>2</sub>D<sub>3</sub> [75]. Together, these observations suggest a model wherein interactions involving 1,25(OH)<sub>2</sub>D<sub>3</sub> and the sex hormones influence the expression of an MS risk gene, for example, *HLA-DRB1\*15*, by an epigenetic mechanism that exhibits inheritance, decay, and female gender bias.

The impact of puberty on MS incidence also demonstrates sexual dimorphism. A seminal study noted an F:M MS incidence ratio of 3.7 after puberty compared with 1.6 before puberty [101]. Additional reports confirmed a two- to threefold increase in the F:M MS incidence ratio after puberty due to increased MS incidence in postpubertal females. Duquette et al. noted “this change at female puberty is so highly significant that it must be related ... to the acquisition of the disease,” and further, “a possible endocrine explanation for the unbalanced sex ratio ... probably acting on T lymphocyte subsets” is implicated. With male puberty, TST increases from 0.2 to ~20 nmol/L, and E2 increases from 0.003 to ~0.05 nmol/L; with female puberty, E2 increases from <0.002 to ~0.4 nmol/L (peak level), and TST increases from 0.2 to 0.8 nmol/L [113]. These data suggest estrus-level E2 increases MS disease risk, whereas rising TST levels have little impact on male MS risk.

Hormone treatment for gender incongruence influenced the subsequent risk of MS differently in transsexual females and males in a small pioneering study performed in the United Kingdom. Unexpectedly, the MS risk was 4.6-fold higher in transsexual females than transsexual males [105]. Treatment for the male → female transition involves administering estrus-level E2 plus an androgen antagonist [114]. Treatment for the female → male transition involves administering TST plus progesterone [115,116]. This small pioneering

**TABLE 101.1** Sexual dimorphism in MS.

Observation	Interpretation	References
The global F:M disease prevalence ratio has risen from 1.4 to >3 due to a rise in female RRMS incidence	Fixed traits such as sex chromosome and sex hormone differences alone cannot explain this trend; instead, an environmental risk factor appears to be acting by a female-biased epigenetic mechanism	[2,6]
MS risk gene penetrance is higher in female than male MS family members	These data implicate sex hormone–gene interactions influencing risk gene expression by a female-biased epigenetic mechanism	[98–100]
The F:M disease incidence ratio is two- to fivefold higher after puberty than before puberty due to a rise in female RRMS incidence	This observation implicates estrous E2 levels ( $\sim 0.4\text{--}0.7\text{ nmol/L}$ serum) in a mechanism that increases female MS risk	[101–104]
Hormonal treatment for gender incongruence resulted in a 4.6-fold higher MS risk for transsexual females than transsexual males	Sex chromosome DNA differences are excluded, and E2 therapy for the male to female transition is unambiguously implicated in a mechanism that increases transsexual female MS risk	[105]
Pregnancy-induced hormonal changes decreased the MS relapse rate $\sim 70\%$ ; postpartum, this rate rebounded to $\sim 170\%$ of the prepregnancy year	Pregnancy-induced hormonal changes are implicated in a mechanism that supports female reproductive success and promotes peripheral immune self-tolerance	[106–108]

study implicates estrus-level E2 in a biological mechanism that increases transsexual female MS disease risk.

Further research is needed on the impact of hormone treatment for gender incongruence as it relates to the subsequent risk of MS. This unique situation constitutes a de facto treatment study in humans, where the effect of the sex hormones is observed independently of the sex chromosomes. In follow-up studies, it will be important to monitor circulating 25(OH)D levels, since population levels tend to vary with ambient solar radiation, and 25(OH)D variation would be expected to influence MS risk.

### 3.3 Pregnancy studies suggest a hormonally triggered reversible mechanism supporting reproductive success triggers MS remissions

Pregnancy studies have yielded additional insights into the relationship between hormones and RRMS disease. The 70% decline in MS relapse rates during pregnancy and the rebound to 170% of the prepregnancy year postpartum is a consistent observation [106]. Pregnancy-induced hormonal changes include a  $\sim 200$ -fold increase in E2 to a peak of  $\sim 75\text{ nmol/L}$  serum. It is not widely appreciated that 1,25(OH) $_2$ D $_3$  also

increases, specifically from 112 pmol/L prepregnancy to 260 pmol/L during pregnancy [117]. These observations suggest a model wherein pregnancy-level E2 and/or 1,25(OH)<sub>2</sub>D<sub>3</sub> participate in a reversible, protective biological mechanism related to reproductive success. This reversibility criterion excludes sex hormone impacts on thymic T lymphocyte development in childhood (but not adulthood) [118]. Pregnancy-level E2 has a well-established role in the expansion of CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells to maintain maternal tolerance to paternal antigens expressed on the fetus [119]. A question remains as to why pregnancy E2 and/or 1,25(OH)<sub>2</sub>D<sub>3</sub> levels correlate with decreased MS disease activity, whereas estrus-level E2 appears to amplify female MS risk. Risk mechanisms and disease activity mechanisms may not fully overlap; this may be one example of a divergence in the risk and disease mechanisms. Alternatively, there may be a core protective mechanism like CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell expansion that can be triggered by pregnancy-level E2 but not estrus-level E2.

In summary, reviewing data on MS sexual dimorphisms and pregnancy suggests the following key features of a biological mechanism tied to sexual disparities in MS. The involvement of 1,25(OH)<sub>2</sub>D<sub>3</sub> in a protective mechanism is suggested by the inverse correlation between two global trends, rising F:M MS incidence ratios and declining population vitamin D status. The likelihood that interactions between 1,25(OH)<sub>2</sub>D<sub>3</sub> and the sex hormones influence risk gene expression by an epigenetic mechanism is suggested by the *HLA-DRB1\*15*-positive MS multiplex family studies. A strong link between estrus-level E2 and elevated female MS risk is implied by the puberty data and the de facto sex hormone treatment study for gender incongruence. Finally, the concept that the protective biological mechanism is reversible, involves pregnancy-level E2 and/or 1,25(OH)<sub>2</sub>D<sub>3</sub>, and leads to the expansion of CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells for reproductive success is suggested by the pregnancy data.

Studies in the EAE model of MS have probed for biological mechanisms that may be involved in MS sexual dimorphisms. These studies were reviewed and illustrated previously [6]. Briefly, ER $\alpha$  and VDR expression in CD4<sup>+</sup> T lymphocytes were necessary for E2 and 1,25(OH)<sub>2</sub>D<sub>3</sub>, respectively, to inhibit EAE induction. Surprisingly, E2-mediated EAE resistance required a functional *Vdr* gene in the CD4<sup>+</sup> T cells [120]. The E2 levels were higher in wild-type mice than in mice with CD4<sup>+</sup> T cells lacking a functional *Vdr* gene, suggesting these T cells either produced E2 or stimulated its production. The E2 decreased *Cyp24a1* transcripts and increased *Vdr* transcripts in the CD4<sup>+</sup> T cells, prolonging the 1,25(OH)<sub>2</sub>D<sub>3</sub> half-life and increasing CD4<sup>+</sup> T cell responsiveness to this hormone. The synergistic E2 and 1,25(OH)<sub>2</sub>D<sub>3</sub> interactions yielded an increased

frequency of CD4<sup>+</sup>Foxp3<sup>+</sup>Helios<sup>+</sup> Treg cells, higher expression of the Foxp3 and Helios proteins, and improved EAE resistance. The EAE data are consistent with a model wherein E2 and 1,25(OH)<sub>2</sub>D<sub>3</sub> interact with *Foxp3* and *Ikzf2* gene enhancer regions to increase transcription by epigenetic mechanisms. Subsequently, the Foxp3 and Helios proteins re-program the activated CD4<sup>+</sup> T cell transcriptome. Finally, the increased frequency and function of CD4<sup>+</sup>Foxp3<sup>+</sup>Helios<sup>+</sup> Treg cells improves the animal's resistance to EAE.

#### 4. CD4<sup>+</sup>FOXP3<sup>+</sup> T regulatory cells and hormonal regulation of FOXP3

##### 4.1 Sexual dimorphisms implicate a hormonally regulated, CD4<sup>+</sup> T cell intrinsic protective mechanism

The MS sexual dimorphism studies and animal modeling experiments suggest there exists a CD4<sup>+</sup> T cell intrinsic mechanism involving 1,25(OH)<sub>2</sub>D<sub>3</sub>, E2, and TST as positive transcriptional regulators of a gene or genes that is/are necessary to prevent autoimmune-mediated damage to the CNS. The hypothesized mechanism would also have an essential function in female reproduction. The human CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells and *FOXP3* and rodent *Foxp3* genes fulfill these criteria. These genes establish the transcriptional identity and function of the CD4<sup>+</sup>Foxp3<sup>+</sup> T cells that prevent autoimmune-mediated CNS damage [121]. Their expression is reversibly regulated by the nuclear steroid hormone receptors VDR [81,122,123], AR [124–126], and ER $\alpha$  [127–130] through epigenetic mechanisms. Finally, selective CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell migration to the fetomaternal interface and replenishment of CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells from the thymus are essential for successful pregnancy [131–133]. In the present section, we briefly review the discovery of CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells and the *Foxp3* gene. We then summarize the CD4<sup>+</sup> T cell heterogeneity and phenotypic malleability, in particular, the influence of 1,25(OH)<sub>2</sub>D<sub>3</sub> and the VDR on the transdifferentiation of CD4<sup>+</sup> Th17 cells into CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells that limit CD4<sup>+</sup> Th17 cell pathogenicity.

##### 4.2 The discovery of CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells and their dysfunction in MS

The discovery of CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells can be traced to experiments probing the role of the thymus in immunological self-tolerance. Early neonatal thymectomy caused autoimmune oophoritis in female mice but not orchitis in males, implying neonatal thymus-dependent enforcement of immune privilege in the ovaries but not in the testes [134]. Transferring a minor

subset of CD4<sup>+</sup>CD25<sup>+</sup> T cells into the athymic females restored ovarian immune privilege and prevented oophoritis [135]. Human studies subsequently confirmed the pathogenic role of CD4<sup>+</sup>CD25<sup>+</sup> T cells in autoimmune disease and the dominant protective role of CD4<sup>+</sup>CD25<sup>+</sup> T cells in autoimmune disease prevention [121]. To our knowledge, no further studies have investigated why immune privilege in the ovary depends on the neonatal thymus but immune privilege in the testes does not. This observation may point to important female–male differences in peripheral CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation.

The spontaneous *Scurfy* mutation in mice led to the discovery of the genetic basis for dominant immunological self-tolerance. The X-linked *Scurfy* mutation causes a lethal autoimmune syndrome in neonatal male mice similar to the autoimmune disease observed in females and males lacking the *Ctla4* or *Tgfb* genes. Genetic analyses linked the *Scurfy* phenotype to the *Foxp3* gene [136,137], so named for its protein product, a new member of the forkhead/winged-helix family of transcription factors [138]. Mutations in the evolutionarily conserved human ortholog, *FOXP3*, are responsible for IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked), a lethal autoimmune disease syndrome of young boys [139,140].

The Foxp3 protein specifies much of the transcriptional signature of CD4<sup>+</sup>CD25<sup>+</sup> Treg cells, now designated CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells [141,142]. Alone, Foxp3 is not sufficient to endow CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells with their suppressive function. Rather, Foxp3 influences the transcription of an unexpectedly large number of CD4<sup>+</sup> T cell genes through its interactions with other transcription factors. The liganded VDR is a positive transcriptional regulator of the *Ikzf2* [15], *Ctla4* [13], and *IL2ra* [86] genes encoding the Helios, CTLA-4, and IL-2RA proteins, respectively, which are among the signature CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell genes needed for suppressive function. The tCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells arise in the thymus and function in central tolerance [121,143], whereas the pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells are induced in the periphery and function in peripheral tolerance and tissue repair [144,145]. Together, these cells enforce dominant tolerance to self, commensal microbes, and fetal antigens. Indeed, research in the EAE model demonstrated the direct involvement of the pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells within the CNS in both the natural recovery from EAE and protection from EAE induction [146]. Importantly, the CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells from MS patients exhibit reduced suppressive function compared with those from healthy controls [147–149].

#### 4.3 1,25(OH)<sub>2</sub>D<sub>3</sub> supports protective pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation

The CD4<sup>+</sup> T cell lineage is remarkably heterogenic. Many differentiated CD4<sup>+</sup> T cell subsets are recognized by the extrinsic cues they sense, the nuclear transcription factors they display, their dominant transcriptional signatures, the immune proteins they produce, and the specific forms of immune defense in which they participate [145,150]. Phenotypic malleability is a signature feature of these diverse CD4<sup>+</sup> T cell types. Individual CD4<sup>+</sup> T cells have been observed to change their phenotype in response to extrinsic cues and intrinsic metabolic states. Moreover, the clonal progeny of individual CD4<sup>+</sup> T cells have been observed to differ phenotypically from their parental clone. This elegant system of phenotypic malleability allows tissue-resident CD4<sup>+</sup> T cells to respond to local microenvironmental cues in a manner that is appropriate to the time and place [151,152].

Phenotypic malleability has been envisioned mechanistically in terms of a bistable state switching model [153]. In this model, there exist two polarized, self-reinforcing CD4<sup>+</sup> T cell states, each with a characteristic gene regulatory network and the capacity to oppose the other state. Cell extrinsic cues such as hormones, pathogens, cell–cell interactions, and soluble mediators serve as potential drivers of transdifferentiation. A complex web of integrated cytosolic signal transduction pathways emanates from local microenvironmental cues and converges in the CD4<sup>+</sup> T cell's nucleus. In response, the constellation of nuclear factors (e.g., chromatin remodelers, transcription factors) either maintains the existing gene regulatory network or initiates reprogramming such that the cell transforms through intermediate states into the alternative CD4<sup>+</sup> T cell state.

A striking example of CD4<sup>+</sup> T cell phenotypic malleability is the interconversion between the CD4<sup>+</sup> Th17 cells that are pathogenic in MS, and the pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells that limit CD4<sup>+</sup> Th17 cell pathogenicity and are dysfunctional in MS [154]. Signaling of 1,25(OH)<sub>2</sub>D<sub>3</sub> to VDR-expressing CD4<sup>+</sup> T cells has a well-established role as an extrinsic signal driving the transformation of CD4<sup>+</sup> Th17 cells into pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells in humans and mice [153,155]. The rapidly emerging field of regenerative immunology has begun to document the benefits of CD4<sup>+</sup> T cell phenotypic malleability beyond immune surveillance by demonstrating the regenerative functions of tissue-resident pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells [144,145]. In a mouse model of MS, the CNS-resident pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells promoted myelin regeneration

independently of their immunoregulatory capacity [156]. Recent reviews summarize a wealth of information on the precise extrinsic cues, intracellular signal transduction pathways, metabolic states, transcription factor networks, and chromatin accessibility states involved in CD4<sup>+</sup> T cell phenotypic malleability [121,150].

The actions of 1,25(OH)<sub>2</sub>D<sub>3</sub> as a driver of CD4<sup>+</sup> Th17 cell transdifferentiation into pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells have been analyzed in human T cell activation cultures. Briefly, 1,25(OH)<sub>2</sub>D<sub>3</sub> and IL-2 addition to T cell activation cultures increased the pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cell frequency and function, particularly for female T cells [157–160]. Similarly, 25(OH)D<sub>3</sub> addition also increased the pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cell frequency and function if myeloid lineage cells were present to produce 1,25(OH)<sub>2</sub>D<sub>3</sub> [161]. These results show that the 1,25(OH)<sub>2</sub>D<sub>3</sub> and IL-2 promoted the genesis of new pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cells and/or the transformation of residual CD4<sup>+</sup> Th17 cells into pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cells. Recent studies probed the question of clonal derivation. When mature pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cells were first removed, 1,25(OH)<sub>2</sub>D<sub>3</sub> and IL-2 addition to the residual T cells increased the pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cell frequency indicating transdifferentiation rather than expansion of alternate clones [162].

Complementary results regarding 1,25(OH)<sub>2</sub>D<sub>3</sub> as a driver of CD4<sup>+</sup> Th17 cell transdifferentiation into pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells were obtained in rodent EAE studies. In this model, administering a single 1,25(OH)<sub>2</sub>D<sub>3</sub> dose [163] or three daily 1,25(OH)<sub>2</sub>D<sub>3</sub> doses [122,163], starting within a day of antigen priming, induced a high frequency of pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cells and prevented EAE disease. Conditional *Vdr* gene targeting in CD4<sup>+</sup> T cells completely abrogated this effect, demonstrating that these cells were direct targets of 1,25(OH)<sub>2</sub>D<sub>3</sub> action [81]. More recent research identified the source of the 1,25(OH)<sub>2</sub>D<sub>3</sub> that is utilized by VDR-expressing CD4<sup>+</sup> T cells in vivo. Supplementary vitamin D<sub>3</sub> inhibited EAE disease induction only in female mice [13]. In these mice, conditional *Cyp27b1* gene targeting in myeloid lineage cells completely blocked the appearance of CNS-infiltrating pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cells and decreased vitamin D<sub>3</sub>-mediated protection from EAE disease. Conditional *Cyp27b1* gene targeting also decreased the CTLA-4 protein in the pCD4<sup>+</sup>FoxP3<sup>+</sup> Treg cells. These and other results [164] show that *Cyp27b1*-expressing microglia produced 1,25(OH)<sub>2</sub>D<sub>3</sub> for paracrine signaling to CNS-infiltrating CD4<sup>+</sup> T cells, and further, the *Ctla4* gene, like the *Foxp3* and *Ilkzf2* genes, appeared to be a target of 1,25(OH)<sub>2</sub>D<sub>3</sub> and VDR transcriptional control.

#### 4.4 Androgens and estrogens support protective pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation

Androgens and estrogens also influence pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation. Androgen hormone metabolism, the X-linked *AR* gene, and the functions of the nuclear *AR* in immune suppression have been reviewed elsewhere [165]. In mice, administration of dihydrotestosterone (dihydro-TST) increased EAE disease resistance [166–168]. Importantly, unlike testosterone (TST), dihydro-TST cannot be metabolized to E2. Furthermore, a small pilot study in men with RRMS demonstrated that TST treatment slowed brain atrophy on magnetic resonance imaging (MRI) [169,170]. Recent research demonstrated that conditional *Ar* gene targeting specifically in CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells increased the inflammatory response of male mice to allergen challenge in an asthma disease [126]. Further experiments confirmed that TST-*AR* signaling in CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells stabilized *Foxp3* protein expression and increased CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell function.

Estrogenic hormones and their nuclear hormone receptors, ER $\alpha$  and ER $\beta$ , have complex immunoregulatory roles that include support for pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation [91]. Pioneering animal modeling experiments initially demonstrated a striking ability of E2 to increase EAE resistance [171,172]. The E2 inhibited encephalitogenic T cell differentiation and trafficking into the CNS and exerted neuroprotective effects on axons and the myelin sheath. These E2 protective effects correlated with upregulation of *Foxp3* gene expression and pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation [173]. Gene targeting experiments revealed that ER $\alpha$  signaling in CD4<sup>+</sup> T cells was necessary and sufficient for E2-mediated upregulation of *Foxp3* gene expression and pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation [127].

The influences of estrogenic hormones on CD4<sup>+</sup> T cell differentiation in humans have been reviewed [91]. A consistent observation is that estrus E2 levels induced proinflammatory CD4<sup>+</sup> Th1 cells producing IFN- $\gamma$  by promoting *Ifng* gene transcription. An intriguing recent observation is that the peripheral blood pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell frequency in nonpregnant women was only one-third of the frequency observed in men [174]. Moreover, the *FOXP3* transcript abundance per cell in nonpregnant women was only one-third of the abundance observed in men. These and other data reinforce the view that estrus E2 levels support proinflammatory CD4<sup>+</sup> Th1 cell differentiation and provide only limited support for pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation.

Recent research has resolved the conflicting results reported for pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell fluctuations during

human pregnancy [130]. A comprehensive analysis of Treg cell dynamics in the peripheral blood of pregnant women was performed wherein naive  $tCD4^+$  Treg cells were identified as  $Foxp3^{lo}CD45RA^+$  and functionally suppressive  $pCD4^+Foxp3^+$  Treg cells were identified as  $Foxp3^{hi}CD45RA^-$  [133]. The intriguing results demonstrated that functionally suppressive  $pCD4^+Foxp3^+$  Treg cells decreased in peripheral blood to a nadir in the second and third trimesters, corresponding with the appearance of these cells at the maternal–fetal interface [131]. Simultaneously, thymic output of naive  $tCD4^+$  Treg cells, coupled with their increased longevity, replenished the peripheral naive  $tCD4^+$  Treg cell pool throughout pregnancy. In conclusion, pregnancy hormones support thymic naive  $tCD4^+$  Treg cell output and longevity and selective migration of mature  $pCD4^+Foxp3^+$  Treg cells to the maternal–fetal interface to enforce fetal tolerance.

Clearly, *FOXP3* and rodent *Foxp3* gene expression is crucial for the transdifferentiation of encephalitogenic  $CD4^+$  Th17 cells into dominant immunosuppressive  $pCD4^+Foxp3^+$  Treg cells. These cells promote myelin repair and regeneration in the CNS independently of their dominant immunosuppressive capacity. In the CNS tissue, the activated microglial cells are the source of the  $1,25(OH)_2D_3$  for paracrine signaling to CNS-infiltrating  $CD4^+$  T cells. Moreover, the  $pCD4^+Foxp3^+$  Treg cells are essential for successful female reproduction. The placenta is the source of the  $1,25(OH)_2D_3$  in pregnant females [175]. The  $1,25(OH)_2D_3$ , TST, and pregnancy-level E2 are independently capable of enhancing *FOXP3* and *Foxp3* gene transcription. The question arises, could differential  $1,25(OH)_2D_3$ , TST, and E2 enhancement of *FOXP3* gene transcription in males and females be a mechanism linking declining  $25(OH)D$  status with increasing MS risk in a female-biased manner?

## 4.5 Hormonal regulation of the *FOXP3* gene

The evidence presented before demonstrated that between the 1930 and 1989 birth cohorts, the overall MS incidence ratio increased, and further, the composite F:M MS incidence ratio increased from 1.9 to 4.6 in high latitude countries ( $>45$  degrees), and from 1.5 to 2.3 in low latitude countries ( $<45$  degrees) [94]. To achieve these ominous benchmarks, the underlying mechanisms would need to exhibit strong amplifying effects and functional impacts in multiple tissues. Collectively, the sexual dimorphism observations summarized in Table 101.1 implicate sex hormone involvement in one or more underlying mechanisms. Finally, the coincidental precipitous decline in population vitamin D status suggests the hypothesis that this may be a contributing factor [7].

There is abundant evidence for  $1,25(OH)_2D_3$ -mediated regulation of many immune system cells, CNS-resident cells, chemokines, cytokines, growth factors, cell surface receptors, costimulatory molecules, immune checkpoint molecules, signal transduction pathways, nuclear transcription factors, and epigenetic mechanisms. Given the myriad possibilities, we sought to develop a theoretical mechanism that might apply, and even if wrong, might serve as a prototypical mechanism to illustrate how reduced  $1,25(OH)_2D_3$  signaling in combination with sex hormone involvement could contribute to the growing F:M MS incidence ratio. To this end, we focused on regulation of the *FOXP3* gene.

The *FOXP3* protein directly transactivates hundreds of  $CD4^+$  T cell genes, some of which are themselves transcriptional activators [142]. Moreover,  $pCD4^+Foxp3^+$  Treg cells impact dozens of tissues [145]. Given these facts, it seems possible that differential  $1,25(OH)_2D_3$ -mediated regulation of the *FOXP3* gene in females and males might have a strong enough amplifier effect and a broad enough functional outcome to achieve the female MS gender bias that has been recorded. Consequently, we developed a hypothetical model for differential  $1,25(OH)_2D_3$ -mediated enhancement of *FOXP3* gene transcription in women and men. This model may be incorrect. Even so, it may be instructive in future searches for correct mechanisms.

Substantial evidence indicates that  $1,25(OH)_2D_3$  promotes encephalitogenic  $CD4^+$  Th17 cell transdifferentiation into immunosuppressive  $pCD4^+Foxp3^+$  Treg cells in part by enhancing *FOXP3* gene expression. *FOXP3* gene regulation involves epigenetic remodeling and topological association of activated enhancer domains with the gene promoter to set a transcriptional threshold. Several *FOXP3* enhancer domains harbor steroid hormone receptor-responsive elements that serve as de facto hormonal control regions for  $1,25(OH)_2D_3$ , TST, and E2. Here, we consider how the hormonal control regions might affect the topological association of enhancer domains with the promoter such that reduced  $1,25(OH)_2D_3$  signaling would have a more negative impact on *FOXP3* gene transcription and  $pCD4^+Foxp3^+$  Treg cells in females compared with males.

To develop the conceptual framework, we first review *FOXP3* gene structure and the *cis*-regulatory elements that activate the promoter [176]. We then summarize the interactions of the three nuclear steroid receptors, VDR [123], AR [125], and  $ER\alpha$  [130], with their respective hormonal control regions. Finally, we present a holistic model wherein  $1,25(OH)_2D_3$ –VDR signaling could be redundant in males due to the proximity of the VDR and AR response elements within a particular enhancer region that is crucial for  $CD4^+$  Th17 cell transdifferentiation and  $pCD4^+Foxp3^+$  Treg cell stability. Because this particular enhancer lacks an  $ER\alpha$  response element, the

1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling would be indispensable for its activation in females.

The highly conserved human *FOXP3* and murine *Foxp3* genes reside within syntenic X-chromosome regions. The promoter upstream of the first *FOXP3* coding exon controls gene expression in response to TCR and IL-2 signaling [177]. Comparative DNA sequence analysis of *Foxp3* genes in placental mammals identified four conserved, noncoding sequences, CNS0, CNS1, CNS2, and CNS3 (Fig. 101.1) [178–180]. The CNS0, CNS1, CNS2, and CNS3 regions encompass distal enhancers, also known as *cis*-regulatory elements [181].

The pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells in the periphery are regulatory chameleons [145]. They utilize signals present in their local tissue environment to adapt their transcriptional signature to perform tissue homeostatic functions that extend beyond immune tolerance. A cell's transcriptional identity is established and maintained by the specific activity of the *cis*-regulatory DNA elements, including promoters, where RNA polymerase II transcription initiation complexes assemble at the transcriptional start site (TSS), and enhancers that determine RNA polymerase II loading and/or release [182]. Signals present in the pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell's microenvironment determine which proteins are bound to the *Foxp3* gene's *cis*-regulatory elements. Enhancer–promoter connectivity is achieved by long-distance chromosomal DNA looping as protein-activated *cis*-regulatory elements and promoters come into close proximity with the TSS to form large topologically associated structures. An elegant analysis of chromosome conformation, chromatin accessibility, and Foxp3 binding to enhancer–promoter loops at the single cell level in mice with and without a functional *Foxp3* gene revealed that the Foxp3 protein directly transactivated hundreds of Treg-specific genes, including genes like *Irf2* that are themselves master transcriptional regulators [142]. The remarkable ability of pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells to perform tissue homeostatic functions in addition to immune regulation reflects this complex transcriptional rewiring in response to signals present in the tissue microenvironment. Depending on the tissue, some of these signals will be hormonal in nature.

The *Foxp3* gene promoter is first activated in early stages of thymic development (Fig. 101.1A) [180,183,184]. The CNS0 region upstream of the *Foxp3* gene promoter and the intergenic CNS3 region downstream from exon 1 were necessary for this step, since their deletion resulted in a lethal autoimmune syndrome akin to the *Scurfy* phenotype. The CNS0 region did not demonstrate enhancer activity. However, prior to TCR signaling, it carried the H3K4me3 and H3K9/14Ac epigenetic marks indicative of a poised enhancer, suggesting it functions as an epigenetic switch to open the *Foxp3* locus for transcription. The pioneer factor SATB1

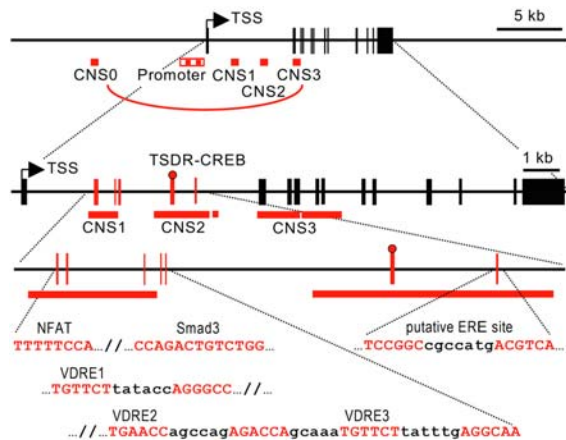

bound to a site in CNS0 (Fig. 101.1B). Disruption of the *Satb1* gene in T cells severely impaired *Foxp3* gene expression and CD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell development. Subsequent TCR and CD28 signaling and c-REL binding to CNS3 initiated sequential DNA looping to bring the CNS0 and CNS3 regions together with the promoter in a topologically associated structure that culminated in *Foxp3* gene transcription.

The CNS1 enhancer region downstream of the promoter is important for extrathymic *FOXP3* gene expression, particularly in T cells associated with mucosal surfaces (Fig. 101.1B) [176,180,185]. CNS1 is not needed for tCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell development. Transforming growth factor-beta (TGF-β) signals activate SMAD3 binding to a conserved site in CNS1 (Fig. 101.1C). Deleting the SMAD3 site decreased pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells in the gut-associated lymphoid tissue, but had no impact on tCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell or pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation [186]. A recent review summarizes the copious literature on TGF-β-mediated control of pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell transdifferentiation [187].

The CNS1 enhancer region is a very recent and remarkable addition to the genome of placental mammals [188]. It is completely missing in nonplacental mammals. An annotated SINE retrotransposon of the mammalian-wide interspersed repeat family encompasses most of the CNS1 enhancer region, suggesting a retrotransposon insertion event abruptly added the CNS1 enhancer to the *FOXP3* gene early in mammalian evolution. Its subsequent retention throughout eutherian mammalian evolution prompts the question does CNS1 contribute to the reproductive success of placental mammals? CNS1 deletion studies in mice suggested the answer was yes. Abundant offspring were produced when wild-type females mated with allogeneic or syngeneic males, and when CNS1-deficient females mated with syngeneic males. However, there was a high rate of embryo resorption when CNS1-deficient females mated with allogeneic males. Embryo resorption correlated with a paucity of pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells, and T cell infiltration and inflammatory pathology of the placenta. These findings indicate an aggressive T cell response to paternal antigens on the fetus. Thus, the CNS1 enhancer increased reproductive success by promoting pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell generation to mitigate maternal–fetal immune conflict.

Knowledge of the *FOXP3* gene CNS1 enhancer's contribution to female reproductive success suggests that hormones associated with the maternal–fetal interface may serve as cell-extrinsic enhancer activation signals. The 1,25(OH)<sub>2</sub>D<sub>3</sub> is one of these hormones [175]. Three vitamin D–responsive elements (VDREs) have been identified in the CNS1 region (Fig. 101.1D) [123]. The 1,25(OH)<sub>2</sub>D<sub>3</sub> addition to human primary CD25<sup>+</sup>CD4<sup>+</sup> T cell stimulation cultures yielded a dose-

**FIGURE 101.1** Human *FOXP3* gene transcriptional regulation and a hypothetical model to explain sexual dimorphisms in MS. (A) Genomic organization of the human *FOXP3* gene (NC\_000023.11). The transcriptional start site is labeled TSS. The eleven coding exons are shown as filled black boxes. The four conserved noncoding sequences are shown as filled red boxes numbered CNS0, CNS1, CNS2, and CNS3. The promoter region is shown as a checked red box. The red arc indicates a superenhancer formed by CNS0 and CNS3. TSDR, Treg-specific demethylated region; CREB, cyclic-AMP response element; NFAT, nuclear factor of activated T cells; VDRE, vitamin D response element; ERE,

dependent induction of pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells. Reporter assays comparing *FOXP3* promoter vectors with and without CNS1 demonstrated a threefold increase in promoter activity when 1,25(OH)<sub>2</sub>D<sub>3</sub> was added to these cultures. No VDRE activity was detected outside the CNS1 region. Further experiments identified VDR–RXR binding to DNA fragments from the CNS1 region. Systematic mutational analyses, VDR–RXR binding experiments, and promoter activation studies ultimately defined the three VDREs. The first of these, VDRE1, is 75% conserved between human and mouse (C.E.H. unpublished).

The three VDREs in the human *FOXP3* gene CNS1 region are important for successful pregnancy in women. The mother's serum 25(OH)D concentration correlated directly with the *FOXP3* transcript abundance and the pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell frequency in the placental tissue [189]. The placenta produces 1,25(OH)<sub>2</sub>D<sub>3</sub> [175]. This production was so robust that the mother's serum 1,25(OH)<sub>2</sub>D<sub>3</sub> level increased about 2.5-fold [117]. A recent review and metaanalysis calculated that miscarriage rates were nearly twofold higher in vitamin D–deficient women compared with vitamin D–replete women [190]. Together, the evidence suggests that vitamin D–replete status, placental 1,25(OH)<sub>2</sub>D<sub>3</sub> production, and VDR binding to the three VDREs in the human *FOXP3* gene's CNS1 enhancer are important for successful pregnancy. We refer interested readers to Chapter 32, "Vitamin D and Pregnancy," Chapter 34, "Vitamin D and the Placenta," and Chapter 39, "Vitamin D: Role in Reproductive Biology and Dysfunction in Women" for additional information on vitamin D and female reproduction.

Dihydro-TST also activates the human *FOXP3* gene CNS1 enhancer [125]. Reporter assays were performed in embryonic kidney cells (HEK-293) that were cotransfected with a *FOXP3* promoter vector with or without CNS1, and an AR expression construct. In this system, dihydro-TST addition increased promoter activity threefold only when the CNS1 region was present. Further experiments demonstrated AR binding to a DNA

fragment from the CNS1 region (Fig. 101.1E). Subsequent mutational analyses identified the 15 bp AR response element (ARE). Comparative DNA sequence analysis did not reveal conservation of this ARE in the mouse, but possible ARE half sites were observed (C.E.H. unpublished). Dihydro-TST also stimulated AR recruitment to the ARE in CNS1 of the *FOXP3* gene in primary human pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells from the peripheral blood of young men and women. The liganded AR binding increased acetylated-H4 in the area of the ARE, consistent with gene activation. This binding had no impact on two repressive epigenetic marks, methylation of H3K27 or methylation of DNA. Interestingly, *FOXP3* gene expression was more responsive to in vitro dihydro-TST addition in pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells from young women than young men. In the women, responsiveness of the *FOXP3* gene to dihydro-TST addition correlated with serum E2 and menstrual cycle stage. One interpretation of this gender-specific effect is that dihydro-TST activated the CNS1 enhancer that was dormant in pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells from young women but already activated in the cells from young men.

The CNS2 region in the first intron of the *FOXP3* gene exhibits strong enhancer activity. This region is noteworthy for a Treg-specific demethylated region (TSDR) observed in tCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell development (Fig. 101.1A) [191,192]. The TSDR served as an epigenetic mark for stable tCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells, since these CpG sequences were fully methylated in effector CD4<sup>+</sup> Th17 cells, even those that transiently expressed *FOXP3* [193]. Deletional analysis revealed that CNS2 was not essential for *Foxp3* expression in the thymus, but was essential for stable *Foxp3* expression in mature, dividing tCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells [180]. The CNS2 region is the site of an autoregulatory loop. The Foxp3 protein transactivated this CNS2 region in a Runx1-dependent manner to ensure stable *Foxp3* expression.

The CNS2 region is also noteworthy as an E2-responsive region. Potential E $\alpha$ -binding sites were mapped within the cis-regulatory elements of the

estrogen response element; ARE, androgen response element. (B) Factors that regulate *Foxp3* gene transcription are shown in red boxes with arrows pointing to the regions where the transcription factors bind. (C) The NFAT and SMAD3 target sequences within CNS1 are shaded in a sequence comparison between human and mouse. This region is 88% conserved. (D) The VDRE1 target sequence within CNS1 is shaded in a sequence comparison between human and mouse. This region is 85% conserved. (E) The ARE target sequence within CNS1 is shaded (NG\_007392.1; 6683–6697). The full ARE is not conserved in mouse although half elements may be present. (F) The ERE full target site and one ERE half site within CNS2 are shaded. The region encompassing the ERE full and half target sites is 87% conserved. The remaining six ERE half sites are not shown. (G) Hypothetical models to describe how hormonal control regions might affect the topological association of the CNS1 enhancer domain with the *FOXP3* gene promoter in T lymphocytes. From top to bottom, the illustrations show T lymphocytes in the neonatal thymus, or T lymphocytes in the periphery of the vitamin D–deficient adult male, the vitamin D–deficient adult female, the vitamin D–replete adult female, and the pregnant female. The black line represents the human *FOXP3* gene DNA. The red crescents represent the conserved noncoding sequences (solid red) and the promoter (red checkered). The solid red lines represent a topological association between the CNS0 and CNS3 regions and the gene promoter. The hormone control elements are depicted as colored ovals. These elements are labeled with their respective nuclear steroid receptors in the same color. The colored lines connecting the hormone control elements with the promoter represent a topological association. In the case of the ER $\alpha$ , the line is dot-dash to represent a weak interaction and solid to represent a strong interaction.

*FOXP3* gene using the ChIP-qPCR protocol applied to pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells isolated from the peripheral blood of healthy male donors [129]. The ER $\alpha$  binding was observed within the promoter, and in CNS2 and CNS3, but not CNS1. An in silico search for E2 response elements (EREs) suggested the existence of a full palindromic repeat and an ERE half site in CNS2, a half site in the promoter, two half sites downstream of the TSS, and two half sites in the CNS3 region (Fig. 101.1F). These putative EREs showed 100% sequence conservation between human and mouse. To our knowledge, no further experimentation has established the existence of these putative EREs, the E2 concentrations needed to promote ER $\alpha$  monomer binding, or the contribution of putative EAE half sites and ER $\alpha$  dimerization to *FOXP3* gene transcription.

Assuming the temporal and geographic correlation between decreasing 25(OH)D levels and increasing female MS prevalence represents a causal relationship, we sought a biochemical model to explain this and other MS sexual dimorphisms. The search for a model focused on the CD4<sup>+</sup> Th17 cell to pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell transformation, the *FOXP3* gene, and the *cis*-regulatory elements that interact with the gene promoter to set the transcriptional threshold. Before, we reviewed preliminary reports that 1,25(OH)<sub>2</sub>D<sub>3</sub>, TST, and E2 exert hormonal control over *FOXP3* gene transcription. The placement of the hormonal control regions within the *cis*-regulatory elements of the human *FOXP3* gene is significant. Three VDREs and an ARE, but no EREs, map within the CNS1 region, whereas a putative ERE and an ERE half site, but no VDREs or AREs map within the CNS2 region (Fig. 101.1B–F). The model considers how these hormonal control regions might affect the topological association of the CNS1 enhancer domain with the promoter such that reduced 1,25(OH)<sub>2</sub>D<sub>3</sub> signaling would have a greater negative impact on *FOXP3* gene transcription and pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell stability in females than males.

The model is presented in Fig. 101.1G. The promoter and the four conserved *cis*-regulatory elements are depicted as crescents arranged in a circle, with the DNA strand from 5' to 3' looping out between them. The VDR, the AR, and ER $\alpha$  proteins are labeled adjacent to colored ovals that represent their respective hormone-responsive elements. The uppermost drawing illustrates the core enhancer–promoter topological associations needed for *FOXP3* gene transcription initiation in the neonatal thymus. The red lines connecting the promoter with the CNS0 and CNS3 *cis*-regulatory elements indicate this topological association. For simplicity, the contributions of TCR-CREB, IL-2-STAT5, and TGF- $\beta$ -SMAD3 signaling to *FOXP3* promoter activation are assumed but not shown. Rather, colored lines are shown connecting similarly colored ovals to the promoter to

illustrate the contributions of 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR, TST-AR, and E2-ER $\alpha$  signaling to *FOXP3* promoter activation. The model presumes that *Cyp27b1*-expressing microglia produce 1,25(OH)<sub>2</sub>D<sub>3</sub> for highly localized paracrine signaling to CD4<sup>+</sup> T cells infiltrating the brain and spinal cord.

The vitamin D–deficient adult male illustration is below the neonatal thymus. The model proposes that TST-ARE signaling would activate the CNS1 enhancer region to join the topological association of enhancer domains with the promoter. This CNS1 enhancer activation would occur independently of 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling in males. Thus, the model predicts that because their respective hormone-responsive elements are proximal, the TST-AR and 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signals would be redundant for promoting CNS1 enhancer–promoter interactions. Thus, the TST and 1,25(OH)<sub>2</sub>D<sub>3</sub> are predicted to be redundant for driving the CD4<sup>+</sup> Th17 cell to pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell transformation in the male brain and spinal cord.

The vitamin D–deficient adult female illustration is below the vitamin D–deficient adult male illustration. The model proposes that in vitamin D–deficient females, E2-ER $\alpha$  signaling cannot activate the CNS1 enhancer region to join the enhancer–promoter cluster because there is no putative ERE in CNS1. Although there are putative ERE and ERE half sites in CNS2 and CNS3, estrus E2 levels are too low to activate these *cis*-regulatory elements further, and these elements do not contribute to *FOXP3* transactivation. Moreover, due to vitamin D deficiency, microglia would not have enough 25(OH)D substrate to produce 1,25(OH)<sub>2</sub>D<sub>3</sub> for VDR signaling to activate the CNS1 enhancer region. Thus, the model predicts that in vitamin D–deficient females, the CD4<sup>+</sup> Th17 cells infiltrating the brain and spinal cord for any reason would remain unchecked to orchestrate autoimmune-mediated tissue damage.

The vitamin D–replete adult female illustration is below the vitamin D–deficient female illustration. The model proposes that in these replete females, the *Cyp27b1*-expressing microglia would produce enough 1,25(OH)<sub>2</sub>D<sub>3</sub> for VDR signaling to activate the CNS1 enhancer region to join the topological association of enhancer domains with the promoter. Thus, the CD4<sup>+</sup> Th17 cells infiltrating the brain and spinal cord for any reason would be driven to transdifferentiate into pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells that protect the tissue from autoimmune-mediated damage and promote tissue repair and regeneration.

Finally, an illustration of *cis*-regulatory element interactions with the *FOXP3* promoter in pregnant females is at the bottom of Fig. 101.1G. The model suggests that pregnancy E2 levels would strengthen the CNS2 and CNS3 *cis*-regulatory element interactions with the promoter to maintain thymic output of tCD4<sup>+</sup>Foxp3<sup>+</sup> Treg

cells as observed [133]. Moreover, the model suggests that pregnancy 1,25(OH)<sub>2</sub>D<sub>3</sub> levels would strengthen the CNS1 interaction with the enhancer–promoter complex to promote the *FOXP3*-dependent transformation of CD4<sup>+</sup> Th17 cell into pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells. This result would improve protection and myelin repair and regeneration in the brain and spinal cord as was observed [156].

This hypothetical model for differential 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated enhancement of *FOXP3* gene transcription in women and men has significant limitations. Foremost among them is the lack of evidence for a causal link between the three VDREs and the ARE in the CNS1 region and the transdifferentiation of encephalitogenic CD4<sup>+</sup> Th17 cells into protective pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells in vivo. This is a particularly difficult question to address because VDRE1 shows only partial sequence conservation, and the ARE has no equivalent in the mouse. Without response element conservation, straightforward deletional analyses like those that established the role of the SMAD3 site for pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell stability in the gut-associated lymphoid tissue are not feasible. Unlike the VDRE and ARE sites, the full ERE and ERE half site in CNS2, and the ERE half sites in the promoter, near the TSS, and in the CNS3 region showed 100% sequence conservation between human and mouse. However, in silico analysis suggested the existence of these ERE and ERE half sites, but appropriate experimentation has not demonstrated their function in vitro or in vivo. In summary, there is as yet no in vivo evidence that the VDREs, the ARE, and the EREs have a direct role in *Foxp3* gene transactivation. In the absence of such evidence, it is not possible to evaluate experimentally whether the VDREs and the ARE are redundant in males, and whether the contribution

of the VDREs is essential in females as envisioned in the hypothetical model.

Despite these limitations, the hypothetical model has significant strengths. Foremost among the strengths is the conceptualization of a biochemical mechanism that would explain most if not all of the puzzling MS sexual dimorphisms that have been observed. The idea of a *cis*-regulatory element that can be activated by either 1,25(OH)<sub>2</sub>D<sub>3</sub> or TST in men but only by 1,25(OH)<sub>2</sub>D<sub>3</sub> in women for *FOXP3* expression is sound and conceptually useful in the effort to understand how the loss of 1,25(OH)<sub>2</sub>D<sub>3</sub> signaling could elevate female MS disease risk 4.6-fold compared with men. This model is also consistent with all of the observed MS sexual dimorphisms listed in Table 101.1, and with the pregnancy data. In fact, the model predicts the unanticipated 4.6-fold increased MS disease risk in transsexual females compared with transsexual males. Indeed, the model predicts that elevating an individual's vitamin D status to support 1,25(OH)<sub>2</sub>D<sub>3</sub> signaling before administering hormonal treatments for gender incongruence might reduce the MS disease risk in transsexual females. Lastly, the model predicts that for an individual whose risk score for MS is high [194,195], an effort to evaluate and improve the individual's vitamin D status early on might be rewarded by a divergence between predicted MS risk and observed MS diagnosis rate (Box 101.1).

## 5. Interplay between vitamin D and CD4<sup>+</sup> type 1 regulatory T cells in MS

The vitamin D system has long been known for its immunoregulatory effects, and much of the focus to elucidate the mechanisms of 1,25(OH)<sub>2</sub>D<sub>3</sub> action has

### BOX 101.1

#### Recommendations from the vitamin D perspective concerning MS risk.

##### Which individuals warrant concern?

Individuals who experience neurological symptoms consistent with MS (e.g., episodic vision loss or double vision, sensory symptoms such as numbness or tingling, limb weakness, incoordination, impaired balance or gait, urinary symptoms).

Individuals who have a biological first-degree relative diagnosed with MS.

Individuals with a genetically predicted high risk of MS.

##### What steps can be considered?

Measure circulating 25(OH)D levels to establish a baseline; if this level is low according to the Endocrine Society Guidelines, consider increasing vitamin D<sub>3</sub> nutriture, then retest after a few months (see Chapter 57).

Consider offering educational information on early neurological signs consistent with MS and encourage discussions with the primary care physician if neurological disability signs arise.

been on the downregulation of CD4<sup>+</sup> T effector cell subsets and the increase in pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells, as further discussed before. Another key subset involved in maintaining immune tolerance consists of CD4<sup>+</sup> type 1 regulatory T cells (Tr1), which are characterized by secretion of the immunosuppressive cytokine IL-10. In the previous version of this chapter, the role of 1,25(OH)<sub>2</sub>D<sub>3</sub> in the regulation of IL-10 and Tr1 was discussed. The crucial role of IL-10 in protecting the CNS from inflammation had been well established using animal models of MS. In these models, IL-10 and IL-10R were necessary for protection. Furthermore, human data using T cells from MS patients showed that the CD4<sup>+</sup> Tr1 cells produced less IL-10 than healthy control T cells.

Notably, one pathway of interest from the vitamin D perspective was initiated by the discovery that CD46 ligation caused the IFN $\gamma$ -producing CD4<sup>+</sup> T helper 1 (Th1) cells to transdifferentiate from their proinflammatory phenotype to the IL-10-producing CD4<sup>+</sup> Tr1 cell phenotype. Human CD46 is a transmembrane protein expressed on all nucleated cells that is a central component of the innate immune system; it binds complement fragments C3b and C4b and aids in their inactivation [196]. It also functions as a CD4<sup>+</sup> T cell costimulatory molecule, as summarized in a recent review [197].

A pioneering discovery was the finding that MS patients exhibited a defect in CD46-induced CD4<sup>+</sup> Tr1 cells, as characterized by an impaired production of IL-10 [198–201]. This defect was also observed in a primate EAE model [202]. Moreover, two first reports had shown that dynamic processing of CD46 provided a molecular rheostat to control human T cell activation [203], and further, that addition of 1,25(OH)<sub>2</sub>D<sub>3</sub> partially restored the dysfunctional transdifferentiation switch in MS patient CD4<sup>+</sup> Th1 cells, at least in vitro [160]. Whether this was occurring in vivo was unknown. In this updated chapter, we first summarize the previous data on IL-10, CD4<sup>+</sup> Tr1 cells, and MS and how 1,25(OH)<sub>2</sub>D<sub>3</sub> contributes to CD4<sup>+</sup> Tr1 cell functions. We then discuss novel data suggesting that indeed, 1,25(OH)<sub>2</sub>D<sub>3</sub> acts on the CD46 pathway in CD4<sup>+</sup> T cells from patients with chronic inflammation.

## 5.1 IL-10, CD4<sup>+</sup> Tr1 cell discovery and characteristics

In 1997, a CD4<sup>+</sup> T cell population secreting IL-10, a potent antiinflammatory cytokine, was first reported [204]. These cells secreted mainly IL-10 and some TGF $\beta$ , but lower levels of the other cytokines including IFN $\gamma$ . The T cells secreting this particular cytokine profile could be generated in both mice and humans. Named CD4<sup>+</sup> Tr1 cells, they were proposed to

participate in immune tolerance through the secretion of IL-10 [205]. Of note, although it is widely accepted that IL-10 is mainly an antiinflammatory cytokine, recent studies highlight the proinflammatory role IL-10 may also play when produced by effector T cells, especially CD4<sup>+</sup> Th1 cells, because it promotes their survival in the CNS [206]. It is likely that the source of IL-10, the timing, and the local microenvironment impact its function. This discovery opened up a novel area of investigation to fully understand the role of this potent cytokine. Interested readers are encouraged to see a recent review for more details [207]. Nevertheless, the predominant role of CD4<sup>+</sup> Tr1 cells is to reduce tissue inflammation and autoimmunity by suppressing effector T cell functions [208]. A lack of suitable identifying markers has long hampered the study of CD4<sup>+</sup> Tr1 cells [209,210]. Transcriptomics analysis of IL-10-secreting T cells showed their heterogeneity. However, current methods define CD4<sup>+</sup> Tr1 cells with the highly suppressive phenotype by expression of several immune checkpoint inhibitors (LAG-3, PD-1, CTLA-4, TIM-3, TIGIT), the chemokine receptor CCR5, the integrin CD49b, and LAG3 on IL-10-producing Foxp3<sup>+</sup> CD4<sup>+</sup> T cells [211].

## 5.2 CD4<sup>+</sup> Tr1 cells and MS

As discussed in the previous version of this chapter, several studies have highlighted the key role of the IL-10-producing regulatory T cells in the murine EAE model of MS. The essential role of IL-10 has clearly been demonstrated by the initial studies showing that IL-10-deficient mice exhibit significantly increased EAE severity [212]. In contrast, mice expressing the human IL-10 transgene under the control of a class II major histocompatibility complex (MHC) promoter are resistant to EAE [213]. Hence the IL-10/IL-10R axis is necessary to protect the CNS from inflammation in this model.

In MS, increased IL-10 production is associated with remissions and is induced by IFN $\beta$  treatment [208]. Importantly, myelin-reactive T cells from healthy donors produced more IL-10 than MS patient T cells [214], supporting the view that IL-10 suppressed autoreactive T cells in healthy donors and was indeed critical in the maintenance of immune homeostasis. A novel study following the percentage of pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells and CD4<sup>+</sup> Tr1 cells in MS patients receiving IFN $\beta$  treatment reported that the CD4<sup>+</sup> Tr1 cell frequency constantly increased in patients with stable MRI scans, while patients with new lesions exhibited an increase in the percentage of Tr1 only in the first year of therapy [200].

Hence, manipulating CD4<sup>+</sup> Tr1 cells as therapeutic agents to restore tolerance is actively being investigated

[208]. The cytokine IL-27 induced CD4<sup>+</sup> Tr1 cells in both mice and humans [215–217]. In humans, CD4<sup>+</sup> Tr1 cells were also induced by coligation of the TCR and CD46, which induced CD4<sup>+</sup> Th1 cell differentiation, followed by a switch from the proinflammatory Th1 phenotype to the CD4<sup>+</sup> Tr1 phenotype, characterized by increased IL-10 production and reduced IFN $\gamma$  secretion [218,219]. This approach is ineffective in mice, because CD46 expression is restricted to cells in the testis and the eyes. In addition to its complement receptor function, CD46 acts as a docking receptor for many pathogens [220], including two viruses associated with MS, human herpes-virus 6 (HHV-6) [221,222], and cytomegalovirus (CMV) [223]. Ligation of CD46 on CD4<sup>+</sup> Tr1 cells serves as a link between innate and adaptive immunity, since it controls T cell activation, differentiation, polarity, and metabolism, as further discussed in recent reviews [197,224].

Two crucial discoveries focused intense interest on CD4<sup>+</sup> Tr1 cells in the context of vitamin D and MS. Firstly, MS patients exhibited a defect in CD46-induced Tr1 cells that were characterized by impaired production of IL-10 upon CD46 activation [198–201]. Secondly, 1,25(OH) $_2$ D $_3$  treatment of CD4<sup>+</sup> T cells from MS patients and healthy controls profoundly amplified the IL-10-producing phenotype of CD46-costimulated CD4<sup>+</sup> T cells, while concomitantly decreasing IFN $\gamma$  production [160]. This transdifferentiation was further described as a 1,25(OH) $_2$ D $_3$ -driven biological switch (see Fig. 101.2 in Ref. [153]). The bistable switch model envisioned the CD4<sup>+</sup> Th1 cells and CD4<sup>+</sup> Tr1 cells as two immune states, proinflammatory and antiinflammatory, each of which is characterized by a particular gene regulatory network that enables the cell to respond to external stimuli in a biologically appropriate manner. Each type of cell produces an autocrine growth factor that reinforces its own survival. Moreover, each type of cell produces a cytokine that impedes transdifferentiation to the opposing cell type. External microenvironmental stimuli, for example, 1,25(OH) $_2$ D $_3$ , other hormones, pathogen-associated molecular patterns, cytokines, metabolites, and cell–cell interactions, serve as switch inputs to drive transdifferentiation to the alternate T cell state. The biological benefit of such a switch is that it permits a rapid reprogramming to an alternative gene regulatory network, possibly by epigenetic mechanisms, allowing a quick and appropriate response [153].

Mechanistically, it was shown that TCR activation led to a change in the glycosylation of CD46 that favored the recruitment of CD46 to the immune synapse, a key step for its regulatory function, and these glycosylation changes appear to be dysregulated in MS T cells [203]. Importantly, previous research demonstrated a gene–environment interaction mechanism in MS that involved dysregulated N-glycosylation of membrane

proteins [225]. In MS, interleukin-7 receptor variants led to MGAT1 downregulation and a failure of membrane protein N-glycosylation. Testing this mechanism by gene targeting in the EAE model revealed an essential role for the N-glycan branching enzyme, MGAT1, to prevent T cell hyperactivity and spontaneous inflammatory demyelination and neurodegeneration. Testing this mechanism in vitro with activated T cells from MS patients demonstrated that 1,25(OH) $_2$ D $_3$  addition significantly enhanced *MGAT1* transcripts, counteracted MGAT1 downregulation, and restored membrane protein N-glycosylation. The involvement of 1,25(OH) $_2$ D $_3$  in the glycosylation of CD46 that enhances its recruitment to the immune synapse clearly warrants further study in the context of improving CD4<sup>+</sup> Tr1 cell function in MS patients.

Increased levels of soluble CD46 are found in the serum and CSF of MS patients, which may correlate with the activation state of their T cells [226]. It is possible that HHV-6 triggers the CD46 pathway in MS, since associations between HHV-6 infection and active MS have been described, and complexes of HHV-6 bound to soluble CD46 have been isolated from MS sera [227,228]. Many if not most MS patients have low vitamin D status including among others those of European [229,230], African [231], Hispanic [232], and Iranian [233] descent. Together, these observations suggest the hypothesis that virus-mediated triggering of the CD46 pathway in individuals with low vitamin D status might lead to robust CD4<sup>+</sup> Th1 cell differentiation and proinflammatory function that is not properly regulated by CD4<sup>+</sup> Tr1 cell differentiation and function.

### 5.3 1,25(OH) $_2$ D $_3$ modulation of IL-10 and CD4<sup>+</sup> Tr1 cell production

The actions of 1,25(OH) $_2$ D $_3$  with respect to human CD4<sup>+</sup> Tr1 cells have been studied intensively in vitro. The addition of 1,25(OH) $_2$ D $_3$  promoted the CD46 shedding that is required for its regulatory function [203,234]. It also enhanced CD4<sup>+</sup> Tr1 cell differentiation and suppressive function, suggesting that the hormone's antiinflammatory functions occur in part through its effects on CD46 [160]. Furthermore, in MS T cells, 1,25(OH) $_2$ D $_3$  partially restored the CD4<sup>+</sup> Th1 to CD4<sup>+</sup> Tr1 cell switch in vitro and the suppressive ability of these cells [160]. It was proposed that 1,25(OH) $_2$ D $_3$  could act on this bistable Th1/Tr1 switch by altering the dynamics of the system and driving the transition to the Tr1 biological state [153]. These data suggested the existence of cross-talk between the CD46 and 1,25(OH) $_2$ D $_3$  pathways. The 1,25(OH) $_2$ D $_3$  exerts its effects through the VDR, a nuclear hormone receptor

that heterodimerizes with RXR to regulate transcription of target genes (see Chapters 10 and 11).

Importantly, T cell receptor (TCR) signaling via the p38 pathway in naive human T cells induced VDR expression, which then transcriptionally activated the *PLCG1* gene encoding phospholipase C gamma 1 ~ 75-fold [235]. This phospholipase uses calcium as a cofactor to produce inositol 1,4,5-triphosphate, a transducer of receptor-mediated tyrosine kinase signals. The higher *PLCG1* gene expression amplified the effect of further TCR signaling for T cell activation. Novel data show that increased VDR expression is observed upon CD46 T cell costimulation, and more so than in T cells classically activated by CD28 [14]. Furthermore, CD46-costimulated T cells express the  $1\alpha$ -hydroxylase enzyme that produces  $1,25(\text{OH})_2\text{D}_3$  so they are able to utilize the hormone precursor,  $25(\text{OH})\text{D}$  [236]. The cross-talk between CD46 and VDR- $1,25(\text{OH})_2\text{D}_3$  signaling is further evidenced by the striking increase in 24-hydroxylase (which inactivates  $1,25(\text{OH})_2\text{D}_3$ ) by longer-term CD46 costimulation of T cells in the presence of  $1,25(\text{OH})_2\text{D}_3$  [14]. Increased 24-hydroxylase expression is crucial in an autocrine feedback loop that shortens the half-life of bioactive  $1,25(\text{OH})_2\text{D}_3$ , thereby limiting the duration of the hormone response (see Chapter 5). Furthermore, analysis of ex vivo T cells from MS patients receiving supplementary vitamin D exhibited similar phenotypes to what was observed in vitro, suggesting the in vivo activation of the CD46 pathway in humans [14].

These data were further corroborated in a recent study analyzing patients with severe COVID-19, including life-threatening hyperinflammation and acute respiratory distress syndrome (ARDS) [236]. These patients exhibited an enhanced  $\text{CD4}^+$  Th1 cell response with increased  $\text{IFN}\gamma$  but very low IL-10 levels, and enhanced complement response, notably of C3. Together, these observations suggested the  $\text{CD4}^+$  Th1 cells from the COVID-19 patients might be incapable of undergoing the CD46-mediated switch from the proinflammatory  $\text{CD4}^+$  Th1 cell phenotype to the anti-inflammatory  $\text{CD4}^+$  Tr1 cell phenotype for reasons that are not yet clear. In this study, CD46 costimulation of healthy T cells also resulted in increased VDR and  $1\alpha$ -hydroxylase enzyme expression, and this depended on cleavage of intracellular C3. Further experiments characterized the effects of  $1,25(\text{OH})_2\text{D}_3$  on transcriptomic and epigenetic changes in T cells activated by CD28 costimulation. Importantly, CD28 costimulation indirectly activates CD46 by cleavage of C3. Adding  $1,25(\text{OH})_2\text{D}_3$  to the CD28-costimulated T cells induced not only IL-10 but also IL-6, considered a proinflammatory cytokine. The  $1,25(\text{OH})_2\text{D}_3$  promoted IL-10 in an IL-6-STAT3 dependent manner, in agreement with a previous animal study showing that IL-6 promoted IL-10-

producing  $\text{CD4}^+$  T cells with Tr1-like characteristics [237].

To probe the mechanism of VDR action in the  $\text{CD4}^+$  T cells, the epigenetic changes were analyzed using H3K27Ac, a marker of active genome regions, in CUT&RUN experiments. They observed the modulation of superenhancers, allowing the binding of several transcription factors, such as c-JUN, STAT3, and BACH2, which together with VDR shaped the transcriptional response to VDR- $1,25(\text{OH})_2\text{D}_3$  signaling [236]. Importantly, the CD46-stimulated molecular pathways governing termination of proinflammatory  $\text{CD4}^+$  Th1 cell responses were impaired in the  $\text{CD4}^+$  T cells obtained from the bronchoalveolar lavage fluid of patients with severe COVID-19. It is likely that this impairment contributed to hyperinflammation and ARDS. Of note, in this study, no enrichment of  $\text{CD4}^+$  Tr1-specific genes was observed upon  $1,25(\text{OH})_2\text{D}_3$  addition, but this may be due to using CD28 stimulation rather than CD46-stimulation prior to the transcript analysis. Indeed, the analysis of T cells from MS patients who received supplementary vitamin D<sub>3</sub> or placebo clearly showed a preferential effect of  $1,25(\text{OH})_2\text{D}_3$  addition on CD46-activated T cells rather than CD28-activated T cells [14]. Further analysis of  $1,25(\text{OH})_2\text{D}_3$ -mediated effects directly on the CD46 pathway in the  $\text{CD4}^+$  Th1 cells from the bronchoalveolar lavage fluid of COVID-19 patients is urgently needed. Such analysis could yield novel mechanistic insights into how  $1,25(\text{OH})_2\text{D}_3$  directly supports switching of  $\text{CD4}^+$  Th1 cells into the  $\text{CD4}^+$  Tr1 cell phenotype. New insights might reveal why switching of pathogenic  $\text{CD4}^+$  Th1 cells into protective  $\text{CD4}^+$  Tr1 cells appears to be impaired and suggest new approaches to resolve hyperinflammation and ARDS in COVID-19 patients.

Overall, these two studies strongly emphasize the key role of the cross-talk between the CD46 pathway and VDR- $1,25(\text{OH})_2\text{D}_3$  signaling for control of hyperinflammation in humans. Recent work suggests a sufficient vitamin D status before an infection is more important than vitamin D<sub>3</sub> supplementation after infection [238]. Many clinical trials have begun to evaluate the effect of vitamin D<sub>3</sub> supplementation in patients with severe COVID-19. We are aware of the following trials registered at Clinicaltrials.gov: NCT04344041, NCT04411446, NCT04449718, NCT04525820. We refer interested readers to Chapter 99 for further details.

#### 5.4 $1,25(\text{OH})_2\text{D}_3$ as a potential $\text{CD4}^+$ Tr1 cell inducer in MS patients

Due to the highly suppressive function of  $\text{CD4}^+$  Tr1 cells, they are currently being investigated as a potential therapeutic in MS [208]. Since the biologically active

hormone  $1,25(\text{OH})_2\text{D}_3$  triggers  $\text{CD4}^+$  Tr1 cell differentiation in vitro, the question arises could biologically *inactive* vitamin  $\text{D}_3$  (cholecalciferol) supplementation be used to support this  $\text{CD4}^+$  Tr1 cell response in MS patients? In MS, vitamin  $\text{D}_3$  supplementation is safe and has been associated with a modulation of T cell responses. Data on vitamin  $\text{D}_3$  supplementation and immune system responses in vivo as well as effects on MS progression are, however, not consistent.

## 5.5 Summary of the interplay between $1,25(\text{OH})_2\text{D}_3$ and $\text{CD4}^+$ Tr1 cells in MS

It is clear that  $1,25(\text{OH})_2\text{D}_3$  exerts profound effects on cytokine production, promotes the regulatory  $\text{CD4}^+$  Tr1 cell subset, and controls the switch from production of  $\text{IFN}\gamma$  to IL-10. Recent autoantigens such as RASGRP2 have been identified in MS [239,240]. These autoantigens favor autoreactive Th1 cell migration to the brain. Switching these autoreactive  $\text{CD4}^+$  Th1 cells to an IL-10-producing phenotype may therefore dampen the local inflammation in the CNS. It was recently reported that  $1,25(\text{OH})_2\text{D}_3$  favored motility of  $\text{CD46}$ -costimulated T cells toward CXCL11, a ligand of CXCR3 expressed by Th1 cells and driving their migration to the CNS, suggesting enhanced migration of these Th1-switched Tr1 cells toward the CNS [14]. Locally increased IL-10 production might also be beneficial because it regulates microglial activation [164,241]. Therefore,  $1,25(\text{OH})_2\text{D}_3$ -mediated induction of  $\text{CD4}^+$  Tr1 cells in the CNS may also reduce local inflammation through this effect. The  $1,25(\text{OH})_2\text{D}_3$  has been shown to restore the altered  $\text{IFN}\gamma/\text{IL-10}$  switch in  $\text{CD4}^+$  T cells from patients with MS in vitro, and analysis of  $\text{CD4}^+$  T cells from patients supplemented with vitamin  $\text{D}_3$  suggests that the regulatory  $\text{CD46}$  pathway is activated in vivo by the vitamin D pathway.

In mice, an elegant paper showed expansion of  $\text{CD4}^+$  Tr1 cells using nanoparticles coated with autoimmune disease—relevant peptides bound to major histocompatibility complex class II molecules in different mouse models [242]. A combination with vitamin  $\text{D}_3$  may provide a further approach to switch on the IL-10 suppressive program in patients. Because analysis of the human brain is limiting, novel approaches such as the use of brain spheres or organoids may provide a suitable model to study the role of vitamin D compounds in modulating brain and immune cells, as well as their interaction, to provide a full picture of how it modulates brain inflammation.

Mechanistically, there are still many unknowns. Key roles for the transcription factors eomesodermin [243] and Bhlhe40 [244] in controlling the switch from  $\text{IFN}\gamma$  to IL-10 production have been reported. These reports

raise the question whether either of these transcription factors might be involved in the  $1,25(\text{OH})_2\text{D}_3$ -mediated IL-10 switch. Given the demonstrated safety of clinical trials involving vitamin  $\text{D}_3$  supplementation in MS patients, and the overall beneficial outcome in terms of  $1,25(\text{OH})_2\text{D}_3$ –VDR signaling and  $\text{CD4}^+$  T cell activation observed in vitro, it is likely that vitamin  $\text{D}_3$  will benefit MS patients with hypovitaminosis D, although timing early in the disease course may be a key to efficacy.

## 6. Oligodendrocytes, DNA methylation, and the methionine cycle

### 6.1 The vitamin D system supports oligodendrocyte myelin repair and replacement

Interest in vitamin D's neuroprotective effects on mature oligodendrocytes (OLGs) and myelin synthesis was surging when the previous version of this chapter was written. Pioneering experiments performed decades ago hinted at vitamin D's role in mammalian CNS development, function, and repair. The rate-limiting enzyme for  $1,25(\text{OH})_2\text{D}_3$  biosynthesis ( $1\alpha$ -hydroxylase) had been identified in brain sections [74,245], radiolabeled  $1,25(\text{OH})_2\text{D}_3$  binding to multiple sites in the mammalian brain had been demonstrated [246], and  $1,25(\text{OH})_2\text{D}_3$ -mediated stimulation of neurotrophin synthesis had been observed [247,248]. These early studies suggested that  $1,25(\text{OH})_2\text{D}_3$  could be considered a neurosteroid hormone. For more information on these topics, we refer interested readers to Chapter 27 (Vitamin D Brain Development and Function).

The colocalization of the VDR and myelin basic protein (MBP) staining in OLG of the brain and spinal cord prompted the hypothesis that  $1,25(\text{OH})_2\text{D}_3$ –VDR signaling might support myelin biosynthesis [249]. This hypothesis triggered seminal studies on demyelination and remyelination in the MS brain [250]. Serial MRI of RRMS patients revealed a seasonal periodicity in brain demyelinated lesion formation. New lesion numbers were 5.3-fold higher in April than October. Application of similar regression models simultaneously to demyelinating lesions and circulating  $25(\text{OH})\text{D}$  levels in the population showed that both variables varied by season [251]; the two curves showed an inverse correlation, with circulating  $25(\text{OH})\text{D}$  changes leading lesion number changes by  $\sim 2$  months. An MRI study performed a decade later produced an elegant polar plot where new RRMS brain T2 lesion formation was superimposed on ambient solar radiation data [252]. The plot revealed new lesion accrual increased significantly in the Spring after a winter of low solar radiation, and decreased abruptly in

September after a summer of high solar radiation. Published data on circulating 25(OH)D levels in this population [253] also showed an inverse correlation, with circulating 25(OH)D changes leading lesion number changes by  $\sim 2$  months. The VDR expression in OLG, and the striking inverse correlation between circulating 25(OH)D levels and new lesion formation, suggested that 1,25(OH) $_2$ D $_3$ –VDR signaling may protect and restore myelin, and conversely, that hypovitaminosis D may contribute to myelin loss and remyelination failure in the MS brain.

### 6.2 1,25(OH) $_2$ D $_3$ supports the pCD4 $^+$ Foxp3 $^+$ Treg cells that promote myelin repair and replacement

Animal modeling studies tested this hypothesis and began to elucidate the underlying mechanisms. In rodents with EAE disease, 1,25(OH) $_2$ D $_3$  treatment rapidly improved ambulation, decreased brain inflammation, restored myelin architecture, and increased pCD4 $^+$ Foxp3 $^+$  Treg cells [163,254]. These EAE results suggested involvement of pCD4 $^+$ Foxp3 $^+$  Treg cells in the mechanism. Further EAE studies demonstrated 1,25(OH) $_2$ D $_3$ -mediated increases in neural stem cell numbers, immature oligodendrocyte precursor cells (OPC), and mature, myelinating OLGs [255]. More recent EAE data demonstrated that early 1,25(OH) $_2$ D $_3$  treatment controlled neuroinflammation, reduced oxidative stress parameters, preserved myelin, and improved blood–spinal cord barrier function [256]. Research in toxin-based demyelination models showed that 1,25(OH) $_2$ D $_3$  treatment preserved existing myelin and increased new myelin formation [257–259].

New animal modeling studies have probed how pCD4 $^+$ Foxp3 $^+$  Treg cells contribute to neuroprotective mechanisms. As noted before, 1,25(OH) $_2$ D $_3$  drove CD4 $^+$  Th17 cells to transdifferentiate into pCD4 $^+$ Foxp3 $^+$  Treg cells. New data show that CNS-resident pCD4 $^+$ Foxp3 $^+$  Treg cells promoted regenerative functions including remyelination after toxin-induced demyelinating injury [260]. Depleting the pCD4 $^+$ Foxp3 $^+$  Treg cells abrogated OPC differentiation and mature OLG remyelinating activity, and replacing the pCD4 $^+$ Foxp3 $^+$  Treg cells restored this developmental pathway. Moreover, adding pCD4 $^+$ Foxp3 $^+$  Treg cells to murine brain slice cultures before or after toxin-induced demyelination increased the number of mature, myelinating OLG and promoted axon ensheathment. Among the proteins secreted by the pCD4 $^+$ Foxp3 $^+$  Treg cells, CCN3 was indispensable for these beneficial effects. Other work suggested that 1,25(OH) $_2$ D $_3$  increased CCN3 gene transcription in cultured human fibroblasts, but human T cells were not investigated [261]. For

more information on murine pCD4 $^+$ Foxp3 $^+$  Treg cells and CNS remyelination, we refer interested readers to a recent review [156]. In the future, it will be important to probe the relationships between 1,25(OH) $_2$ D $_3$  and human pCD4 $^+$ Foxp3 $^+$  Treg cells and their secreted protein products in the context of myelin repair and replacement by either surviving or new OLG.

### 6.3 VDR signaling enhances oligodendrocyte differentiation and myelin synthesis

The demonstration of high VDR expression in OLG lineage cells, microglia, neurons, and astrocytes in remyelinating MS lesions suggested possible beneficial effects of 1,25(OH) $_2$ D $_3$ –VDR signaling in MS that were not related to immune regulation [262]. Toxin-induced demyelination model systems have been used extensively to probe this possibility, because inflammation does not occur in these models. In one such model, vitamin D–replete animals sustained less axonal damage and loss during the demyelination phase than vitamin D–deficient animals [263]. However, administering 1,25(OH) $_2$ D $_3$  to vitamin D–deficient animals very late in the toxin-induced demyelination/remyelination protocol provided no benefits. During the early remyelination phase, 1,25(OH) $_2$ D $_3$  improved mitochondrial function [264]. Supplementary vitamin D $_3$  promoted neural stem cell proliferation, OPC formation and migration to lesions, and mature, myelinating OLG differentiation within the lesions [265]. Furthermore, antagonizing VDR signaling in rodent cerebellar slice cultures decreased myelination by 52%. Also, antagonizing VDR signaling after toxin-induced demyelination decreased remyelination by 48%. These effects have been attributed to 1,25(OH) $_2$ D $_3$ –VDR signaling in OLG lineage cells independently of immune regulation.

Some controversy surrounds the topic of myelin regeneration in MS patients, specifically, whether it reflects myelin synthesis by surviving, albeit damaged OLG, or by new OLG derived from the OPC pool [266]. There is also debate as to whether remyelination is clinically relevant, since so many axons are lost in the acute inflammatory phase of MS. There is no doubt that myelin repair and replacement is an ongoing process in healthy adults, with OPC differentiation to the mature, myelinating OLG phenotype being a prerequisite [267]. Carbon-dating studies assessed the integration of  $^{14}$ C derived from nuclear testing into OLG genomic DNA and myelin protein in healthy adults [268]. These data showed low-level OLG turnover (0.33%/year) and continuous myelin turnover, supporting the conclusion that new OLGs slowly replace old OLGs in healthy young adults, although this process diminishes with age. The treadmill model of myelin

biosynthesis envisions mature OLGs continuously producing fresh myelin membrane for remodeling, plasticity, and repair [269].

Questions still remain regarding myelin repair and replacement in MS patients. The carbon-dating studies did not detect OLG turnover in MS patients, but there were exceptions. These data were interpreted as a failure of OLG regeneration and myelin remodeling in the MS patients [270]. The data were also interpreted as invalidating the toxin-induced demyelination models, where OLG regeneration and new myelin synthesis after demyelinating injury had been documented. It is important to note the substantial differences inherent in MS and animal modeling research. A limiting factor in MS research is that postmortem samples derive from a single time point in an older individual with late-stage disease, where lesion history or future as regards myelin is uncertain. In contrast, animal modeling provides an opportunity to apply sophisticated gene targeting and lineage tracing tools and precise analytical methods to follow OLG differentiation, myelin sheath formation, and nutritional and microenvironmental influences over time. Some MS patients clearly exhibit remyelination, whereas others do not. This variability likely reflects both genetic and environmental influences. From the vitamin D perspective, it will be important to investigate several parameters that could significantly impact myelin sheath repair and replacement. For example, it would be worthwhile to study the possible influences of sex, vitamin D nutriture (replete vs. insufficient), and the capacity of activated microglial cells to produce  $1,25(\text{OH})_2\text{D}_3$  in the CNS. For a detailed discussion of the controversies surrounding remyelination in MS and the animal models, we refer interested readers to a review [266].

There are many observations that together suggest the hypothesis that  $1,25(\text{OH})_2\text{D}_3$  supports OPC differentiation and mature OLG myelin sheath repair and replacement in RRMS patients. We review three of them here. First, the longitudinal MRI studies summarized before revealed a near perfect inverse correlation (with a 2-month lag) between a period of high ambient solar radiation, a rise to peak  $25(\text{OH})\text{D}$  levels, and the rapid decline of new T2 lesion formation [250–252]. Second, as described before, loss-of-function *CYP27b1* alleles have been associated with MS risk. Third, recent EAE experiments targeted the *Cyp27b1* gene specifically in myeloid lineage cells, including the microglial cells that produce  $1,25(\text{OH})_2\text{D}_3$  in the CNS [13]. This *Cyp27b1* gene targeting completely abrogated vitamin  $\text{D}_3$ -mediated EAE resistance in female mice. This and prior microglial cell studies [164,271] indicate that microglial cell production of  $1,25(\text{OH})_2\text{D}_3$  is essential to protect the CNS from immune-mediated tissue damage. The *Cyp27b1* gene targeting also inhibited CTLA-4

expression by CNS-infiltrating  $\text{CD4}^+$  T cells, which could serve as a critical immunological checkpoint to prevent CNS tissue damage [13]. Juxtaposing these three observations suggests the hypothesis that activated microglial cell  $1,25(\text{OH})_2\text{D}_3$  production and VDR signaling to OPC and OLG promote myelin repair and replacement, and conversely, that hypovitaminosis D contributes to myelin loss and remyelination failure in the MS brain.

#### 6.4 Redox imbalance could undermine 25-hydroxyvitamin D-1 $\alpha$ hydroxylase enzyme activity

These observations raise at least two questions: what signals promote or inhibit microglial cell  $1,25(\text{OH})_2\text{D}_3$  production, and by what mechanisms does VDR signaling promote OLG development for myelin repair and replacement? To the first question, microglial cell *Cyp27b1* gene transcription, extensive experiments have identified the signals that induce nonrenal *Cyp27b1* gene transcription. Those signals include cytokine-mediated immune stimulation, for example, by  $\text{IFN-}\gamma$  [272]. We refer interested readers to Chapter 9.

The question of microglial cell  $1,25(\text{OH})_2\text{D}_3$  production also concerns the enzymatic activity of  $1\alpha$ -hydroxylase, a monooxygenase with a covalently bound cytochrome P450 (CYP450) cofactor. To our knowledge,  $1\alpha$ -hydroxylase enzyme activity in the MS brain has not been adequately examined. However, it is well known that the CYP450 enzymes undergo oxidative damage and inactivation in the context of inflammatory disease [273]. Consequently, there are biochemical reasons to suspect this CYP450 enzyme inactivation rate may be high in the MS brain.

The enzyme's N-terminus is embedded in the inner mitochondrial membrane, where two mitochondrial electron-transport proteins feed  $\text{NADPH}_2$  reducing equivalents via the CYP450 moiety to the substrate in the enzyme active site (see Fig. 101.2 in Ref. [274]). Mitochondrial respiration and the CYP450 catalytic process produce several reactive oxygen species (ROS) including superoxide anion, hydroxyl radicals, singlet oxygen, and peroxides. In MS, profound oxidative damage to nuclear DNA and lipids has been observed mainly in OLG, where damage is associated with evidence of apoptosis [275]. The ROS concentrations are several-fold higher in the mitochondria compared with other subcellular compartments. In inflammatory diseases such as MS, mitochondrial dysfunction increases the rate of ROS generation [276,277]. The ROS molecules oxidize DNA, proteins, and lipids unless they are inactivated enzymatically by reduction. Nitration of Tyr and Cys residues are examples of radical species-induced

protein damage [273]. Many examples of reversible and irreversible CYP450 enzyme inhibition have been reported.

The tripeptide glutathione (GSH; Glu-Cys-Gly) is an important source of reducing equivalents to inactivate ROS and maintain cellular redox balance [278]. However, in the inflamed brain, increased ROS production exceeds GSH-mediated ROS inactivation capacity, leading to excessive oxidative damage to DNA, proteins, and lipids. Protein Cys residues are especially labile to ROS-mediated damage. The  $1\alpha$ -hydroxylase enzyme has 9 Cys residues. One of them, Cys108, covalently binds the CYP450 moiety that is essential for catalytic activity. Another, Cys455, is in the highly conserved Cys pocket, a bulging region that accommodates the bulky CYP450 group (<https://www.uniprot.org/uniprotkb/O15528/entry>). Either S-nitrosation or oxidation ruptured the thiol-CYP450 bond, dissociated the heme, and irreversibly inactivated other enzymes in this class [273]. It is worth noting that other steroid hormone biosynthetic enzymes are also mitochondrial enzymes in the CYP450 family with similarly vulnerable Cys residues [279]. In summary, the inflamed brain is particularly vulnerable to oxidative stress because ROS production exceeds GSH-mediated ROS inactivation capacity, enzymes that produce hormones, maintain redox balance, and control inflammation are easily damaged, and the energy metabolism needed to repair and replace important proteins and structures is reduced [278]. If the  $1\alpha$ -hydroxylase inactivation rate were to be high in the MS brain, then providing supplementary vitamin D<sub>3</sub> to MS patients would not be expected to support OLG myelin repair and replacement, because there would be insufficient active enzyme for 1,25(OH)<sub>2</sub>D<sub>3</sub> biosynthesis.

## 6.5 VDR signaling enhances the methionine cycle, DNA methylation, and oligodendrocyte precursor cell differentiation

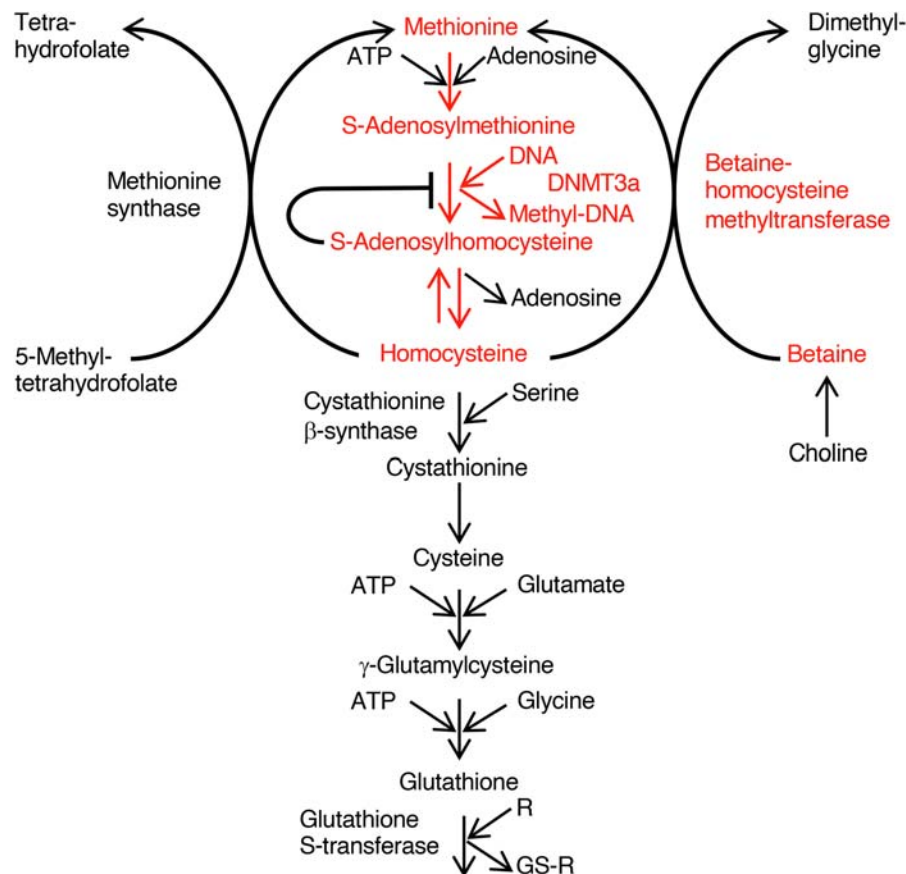

The answer to the second question, what mechanisms allow 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling to promote OLG development for myelin repair and replacement, brings the focus to 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated enhancement of the methionine (MET) cycle (Fig. 101.2). MET, in the form of S-adenosyl-methionine (SAM), provides single carbon units for DNA and protein methylation reactions. DNA methylation is essential to silence the transcriptional repressors that block OLG maturation and myelin synthesis. In the following, we summarize the role of DNA methylation in the OLG developmental pathway and the failure of DNA methylation and OLG development in MS. Then, we review the evidence that nuclear localization of the MET cycle enzyme, betaine-

homocysteine S-methyltransferase (BHMT), is critical for DNA methylation, OLG development, and myelin biosynthesis. Lastly, we review the evidence that 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling enhances *Bhmt* gene transcription, enzyme activity, and DNA methylation in CD4<sup>+</sup> T cells and possibly other cell types [15].

Despite myelin's importance to human evolution, the molecular basis of OLG differentiation and myelin biosynthesis, repair, and replacement functions has only recently been elucidated [267]. It is now clear that complex extracellular signals, intracellular transcriptional networks, and epigenetic mechanisms guide the slow, dynamic process of OPC lineage specification in neural stem cell niches, OPC migration to exposed axons, and OPC terminal differentiation into myelinating OLG. The discovery of transcriptional repressors that maintain OPC in an immature, proliferating state, and transcriptional enhancers that promote OLG expression of essential genes for myelin protein and lipid biosynthesis has been an important achievement. The OPCs that are observed in demyelinated, nonfibrotic MS lesions appear to be blocked from differentiating into mature OLG capable of repairing and/or replacing damaged myelin [280]. As MS disease progresses toward a chronic stage, myelin biosynthesis, repair, and replacement activity gradually become insufficient to maintain myelin sheaths.

This past decade has witnessed a growing appreciation for DNA methylation's involvement in human development and disease generally [281], and in MS specifically [282]. Recent research probing the biochemical basis for blocked OPC differentiation in MS has focused on DNA methylation of the transcriptional repressors that maintain immature OPC in a proliferating state [282]. In the toxin-induced demyelinating model, OLG-specific targeting of DNA methyltransferase genes 1 (*Dnmt1*) and 3a (*Dnmt3a*) decreased remyelinating OLG cell numbers and remyelination efficiency [283]. Two genes encoding transcriptional repressors of OLG development, inhibitor of differentiation-2 (*Id2*) and inhibitor of differentiation-4 (*Id4*), proved to be DNA methylation targets [267]. These gene promoters were hypermethylated and silent in mature OLG. However, blocking DNA methylation induced their expression and prevented mature OLG development, while targeted hypermethylation of these gene promoters silenced transcription and promoted mature OLG differentiation. Thus, *Id2/Id4* promoter methylation was essential for OLG differentiation and myelin protein gene expression in this demyelinating model.

Extending the analysis to humans, the *ID2/ID4* promoter methylation status and mRNA expression were analyzed in postmortem brain tissue samples from MS normal-appearing white matter, MS lesions, and healthy

**FIGURE 101.2 Betaine–homocysteine methyltransferase, the methionine–homocysteine cycle, and DNA methylation.** The central circle red text describes the addition of adenosine to methionine (MET) by methionine adenosyl-transferase to form S-adenosyl-methionine (SAM), the universal methyl donor for all methylation reactions. In the nucleus, SAM is consumed by methylating enzymes like DNA methyltransferase 3a (DNMT3a), which adds methyl groups to particular cytosine residues within CpG clusters. Other methyltransferase enzymes consume SAM to add methyl groups to proteins such as histones and myelin basic protein. Adenosyl homocysteinase reversibly hydrolyzes the methylation reaction product, S-adenosylhomocysteine (SAH), to homocysteine (HCY) and adenosine. If SAH is not hydrolyzed and the HCY removed, the SAH remains bound to the methyltransferase enzyme active site as an end product inhibitor. The HCY can be recycled to MET by two distinct pathways. The most familiar pathway, shown as the half circle on the left, involves 5-methyltetrahydrofolate–homocysteine methyltransferase (MTR), also known as methionine synthase, which transfers a methyl group from 5-methyltetrahydrofolate to HCY. The relatively unknown pathway, shown as the half circle on the right, involves betaine–homocysteine methyltransferase (BHMT), which transfers a methyl group from betaine to HCY. The HCY can also be removed by the ATP-dependent, transsulfuration pathway shown below the central circle. This pathway ultimately yields glutathione (GSH), an important reducing agent for inactivation of cytosolic reactive oxygen species (ROS) generated by mitochondrial respiration.

control white matter [267]. Strikingly, the MS tissue samples exhibited low *ID2/ID4* gene promoter methylation, high *ID2/ID4* gene transcription, and low myelin protein gene expression compared with healthy controls. Thus, incomplete DNA methylation of the repressive *ID2/ID4* genes correlated with a failure of OLG myelin biosynthesis in MS lesions and normal-appearing white matter. These experiments raise critically important questions: what controls DNMT enzyme activity and DNA methylation of repressive genes in the OLG developmental pathway, and why is this activity suboptimal in MS?

## 6.6 1,25(OH)<sub>2</sub>D<sub>3</sub>, the BHMT gene, betaine, and methionine cycle enhancement

One straightforward answer to the first question is that DNMT enzyme activity reflects the availability of its substrate, SAM (Fig. 101.2). SAM is the methyl donor for all methyl group transfer reactions [284]. All methylation reactions generate S-adenosylhomocysteine (SAH) as a reaction product. The SAH remains bound to the enzyme active site as an inhibitor unless it is hydrolyzed to homocysteine (HCY). The HCY can be recycled to MET and then to SAM by the MET cycle. Alternatively,

HCY can be metabolized to GSH by the energy-dependent, transsulfuration pathway. As noted before, GSH is especially important in the brain, where its depletion is associated with many neurodegenerative diseases [278].

If HCY is not recycled to MET or metabolized to GSH, it can be released to the circulation where it is a highly toxic metabolite. Many studies have reported elevated circulating HCY levels in MS patients, particularly in men [16,285–287]. Elevated circulating HCY correlated with MS disease progression [287], cognitive impairment [288–290], depression [291], and brain atrophy [292]. These findings prompted the hypothesis that MS patients may have a defect at some point in the MET cycle, and the resulting elevated circulating HCY levels might contribute to MS by an as-yet-unidentified mechanism. A causal link between elevated circulating HCY levels and damage to the vasculature including the cerebral vasculature has been demonstrated [293]. However, it is not yet clear whether a defect in the MET cycle and elevated circulating HCY levels contribute causally to MS risk or pathogenesis.

The MET cycle offers two biochemical routes from HCY to MET (Fig. 101.2). A well-known route begins with the conversion of dietary folate to N,N-methylene-tetrahydrofolate, and the reduction of this metabolite to N-methyl-tetrahydrofolate by the enzyme N,N-methylene-tetrahydrofolate reductase (MTHFR). Subsequently, 5-methyltetrahydrofolate–homocysteine methyltransferase (MTR; also known as methionine synthase) transfers the N-methyl group from N-methyltetrahydrofolate to HCY, regenerating MET. The MTHFR enzyme, folate, and the cofactor cobalamin have been extensively studied in the context of neural tube birth defects [294].

Less well known is the other biochemical route from HCY to MET, beginning with dietary betaine or choline (which is converted into betaine). The zinc-dependent BHMT enzyme transfers a methyl group from betaine to HCY, regenerating MET. For many years, BHMT was thought to be present only in the liver and the kidney [295,296]. Moreover, since BHMT exhibits rather poor binding constants for its substrates [297], it was believed to be only a minor contributor to the HCY recycling process. However, the observation that BHMT was present and conserved in the genomes of the sea urchin, amphibians, reptiles, birds, and mammals suggested it performed some essential metabolic role [298]. Exciting new evidence has linked nuclear BHMT enzyme expression with DNA methylation and epigenetic silencing of repressive genes in the OLG developmental pathway [17]. Other new evidence demonstrated that 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling promoted *Bhmt* gene transcription in CD4<sup>+</sup> T cells, sparing rodents from developing hyperhomocysteinemia and EAE disease [15]. In

combination, these two important advances suggest the novel hypothesis that 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling supports the function of a nuclear betaine–MET pathway involved in methylation reactions that are critical for epigenetic regulation of gene expression in cells relevant to MS.

Pioneering animal modeling experiments led to the discovery of new biological roles for the betaine–MET cycle. Firstly, recent experiments targeting the *Bhmt* gene in mice found that animals lacking a functional *Bhmt* gene had toxic circulating HCY levels, reduced brain volume, and impaired memory formation [299]. Secondly, other experiments revealed that providing supplementary anhydrous betaine inhibited EAE [300]. Thirdly, betaine, given prior to toxin-induced demyelination, improved brain SAM levels, restored nuclear epigenetic marks, enhanced respiration, and prevented axonal damage in rodents [301]. Fourthly, BHMT protein was identified in the cytoplasm and the nucleus of immature OPC and mature, myelinating OLG in rodent cell and tissue samples [17]. The BHMT, DNMT3a, and histone methyltransferase were in a multi-protein complex bound to DNA.

Human OPC cultures were used to test the functionality of the BHMT–DNMT3a protein complex [17]. The OPCs were chemically treated to induce oxidative damage in the presence or absence of added betaine. The betaine addition increased the stability of the BHMT protein and stimulated OPC differentiation to the mature, myelinating OPG phenotype. Further experiments employed siRNA knockdown of *Bhmt* mRNA in the OPC, followed by culture in the presence or absence of added betaine. Betaine addition increased DNMT3a enzyme activity in control cells, but not in cells with siRNA knockdown of *Bhmt*. Extending their analysis to postmortem MS brain tissue, these investigators detected nuclear BHMT staining in oligodendrocyte lineage cells, possibly OPC, within lesioned areas. These and other data [302] established the functional importance of betaine and BHMT in complex with DNMT3a in the OPC nucleus. In this position, the BHMT could funnel SAM directly to DNMT3a for epigenetic marking. Collectively, these remarkable human and animal results point to a deficiency of betaine and the BHMT enzyme, as well as MET cycle dysfunction, as possible contributing factors in MS pathogenesis. Conversely, the data suggest the exciting possibility that providing betaine and increasing BHMT enzyme expression might improve the MET cycle, restore redox balance, increase respiration, and promote OLG differentiation for myelin repair and replacement in MS patients.

The question arises whether 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling would increase *Bhmt* gene transcription, BHMT enzyme activity, and DNA methylation in CNS-resident cells like OPC and OLG, as it did in murine

CD4<sup>+</sup> T cells. Recent experiments demonstrated that one 1,25(OH)<sub>2</sub>D<sub>3</sub> dose plus supplementary vitamin D<sub>3</sub> reversed EAE disease in mice with transgenic CD4<sup>+</sup> T cells specific for an MBP epitope [15]. This protocol rapidly increased *Bhmt* transcript abundance ~1.6-fold, BHMT enzyme activity ~3-fold, and global DNA methylation in the transgenic CD4<sup>+</sup> T cells. It also increased *Bhmt* transcript abundance in kidney cells. In cultured transgenic CD4<sup>+</sup> T cells, adding 5-aza-deoxycytidine blocked the stimulating effect of 1,25(OH)<sub>2</sub>D<sub>3</sub> on global DNA methylation. These data indicate that a T cell-intrinsic process was responsible for installing methyl marks on new DNA.

Follow-up studies in mice with CD4<sup>+</sup> T cell-specific *Vdr* gene targeting revealed sharply decreased *Bhmt* transcript abundance and BHMT enzyme activity in the *Vdr*-targeted CD4<sup>+</sup> T cells [15]. Unexpectedly, mice with CD4<sup>+</sup> T cell-specific *Vdr* gene targeting and EAE disease had elevated circulating HCY levels. Additional experiments established that CD4<sup>+</sup> T cells did not express the *Mtr* gene encoding methionine synthase. A search algorithm identified a sequence, 5'AGGCCAAGAAGGTGA, with strong homology to DR3-type VDREs that is 100% conserved in the mouse *Bhmt* and human *BHMT* promoter regions. Collectively, these surprising observations indicate that proliferating, myelin-specific CD4<sup>+</sup> T cells must rely on the BHMT–betaine pathway to recycle HCY into MET, since they have no MET synthase–methyl–tetrahydrofolate pathway (Fig. 101.2). When these CD4<sup>+</sup> T cells had no functional VDR, they also lacked the BHMT–betaine pathway. So, they released toxic levels of HCY into the circulation because they could not recycle it.

In summary, new pioneering experiments have greatly advanced our mechanistic knowledge of the vitamin D system's supportive roles in OLG differentiation and myelin synthesis. A direct mechanism has come into focus reflecting 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated enhancement of pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation and tissue homeostatic functions that promote myelin repair and replacement. A second novel mechanism reflects 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling directly in OLG lineage cells independently of immune regulation. Vitamin D–replete animals exhibited improved mitochondrial function, neural stem cell proliferation, OPC formation and migration to lesions, and mature, myelinating OLG within the lesions, whereas vitamin D–deficient animals did not. Further animal experiments demonstrated that promoter DNA methylation of two transcriptional repressors, *Id2/Id4*, allowed rodent OPC to differentiate into myelin-forming OLG. In postmortem MS tissue samples, hypomethylation of the *ID2/ID4* gene promoters correlated with high *ID2/ID4* gene transcription and the absence of OLG expressing *MBP* gene transcripts.

Additional animal experiments revealed a protein complex of BHMT and DNMT3a in the OPC nucleus. This complex transferred single carbon units from betaine to SAM for DNA epigenetic marking. This discovery suggests a novel role for the betaine–MET cycle in epigenetic regulation of gene expression. Finally, research in the EAE model indicated 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signaling enhanced *Bhmt* gene expression, MET cycle function, DNA methylation, and encephalitogenic CD4<sup>+</sup> T cell transdifferentiation into pCD4<sup>+</sup> Treg cells. In combination, these advances suggest the hypothesis that activated microglial cell 1,25(OH)<sub>2</sub>D<sub>3</sub> production and VDR signaling to OPC may promote OLG differentiation for myelin repair and replacement, and conversely, hypovitaminosis D and lack of liganded VDR signaling may contribute to myelin loss and remyelination failure in the MS brain.

## 7. Some reflections on vitamin D<sub>3</sub> supplementation trials in MS

Past clinical trials in MS patients have demonstrated mixed outcomes [303,304]. Those studies have sometimes failed to consider details regarding randomized matching of the treatment and control groups, vitamin D status at enrollment, supplementary vitamin tablet use, vitamin D<sub>2</sub> versus vitamin D<sub>3</sub>, safe and effective vitamin D supplementation protocols, metabolite analytical challenges, power calculations, and many other important aspects of human clinical trial design. Nevertheless, many reports do suggest that vitamin D<sub>3</sub> supplementation promoted anti-inflammatory and regulatory immune parameters, while reducing proinflammatory parameters.

The earliest report, a dose–response study, tested the safety of 4000 to 40,000 IU/day for 28 weeks in MS patients [305]. Circulating 25(OH)D levels in some patients reached twofold higher than the physiologic range with no evidence of hypercalcemia or hypercalciuria, whereas other patients exhibited only a limited increase in this metabolite. The authors concluded that 10,000 IU/day was “safe by a large margin.” Fifteen years later, it is now clear that circulating 25(OH)D levels are under genetic control (see Chapter 60), and some of these genetic variants are risk factors for MS (see previous discussion). New insights might be gained in forthcoming vitamin D supplementation trial designs if baseline and longitudinal 25(OH)D levels were to be measured, if enrollment were to be limited to MS patients with hypovitaminosis D, and if genetic variants that regulate circulating 25(OH)D levels were to be investigated in MS patients who do not exhibit the anticipated increase in circulating 25(OH)D.

There has been considerable debate regarding the thresholds for vitamin D deficiency, insufficiency, and adequacy. Defining optimal 25(OH)D levels from the nutritional perspective has proven to be difficult, but defining this parameter biochemically is straightforward [306]. The vitamin D-25-hydroxylase responds to a broad range of vitamin D<sub>3</sub> concentrations in a biphasic manner. When vitamin D concentrations are low, the 25-hydroxylase produces 25(OH)D rapidly with first-order reaction kinetics, indicating the supply of substrate does not saturate the available enzyme. However, when vitamin D<sub>3</sub> is >15 nmol/L and 25(OH)D is >80 nmol/L, the enzyme produces 25(OH)D slowly with zero-order reaction kinetics. These data indicate that the product, 25(OH)D at >80 nmol/L, is impeding the enzyme active site. Interestingly, evolution appears to have optimized human biology to function with 80–115 nmol/L of 25(OH)D as the physiological level [307]. Consequently, 80–115 nmol/L of 25(OH)D is considered by many, including us, to be optimal for human health.

There has also been controversy regarding how to achieve adequate circulating 25(OH)D levels in individuals and populations. Given individual genetic variations that influence circulating 25(OH)D levels, it is difficult to make a recommendation at the population level. For this reason, some experts now advocate for the concept of a personalized vitamin D response index to assess supplementation efficacy [308]. A thorough critique of this complicated topic is beyond the scope of this chapter. Instead, we refer interested readers to Chapter 57, and to the following reviews for precise details in the MS field [309,310]. It is imperative to note that life-threatening vitamin D intoxication in humans can result from ingestion of extremely high vitamin D<sub>3</sub> doses, for example, >100,000 IU/day, due to untested, unconventional protocols for MS treatment [311].

Investigators anticipate that the results of ongoing trials with earlier interventions and more robust clinical trial designs may shed light on the actual role of vitamin D<sub>3</sub> supplementation in delaying or preventing an MS diagnosis. One ongoing trial is the D-Lay trial (*trial NCT01817166; D-Lay-MS - Efficacy of Cholecalciferol (Vitamin D3) for Delaying the Diagnosis of MS After a Clinically Isolated Syndrome*), testing supplementation in French patients with clinically isolated syndrome. Clinically isolated syndrome refers to individuals who have experienced a first episode of neurological disability caused by inflammatory demyelination; formal diagnosis of MS requires evidence of multiple attacks, affecting distinct portions of the central nervous system. Evidence for such dissemination in space and time can come from clinical relapses or from specific MRI changes. CSF-specific oligoclonal bands can serve as a substitute for dissemination in time [312]. The D-Lay

trial aims to provide a placebo or 100,000 IU of supplementary vitamin D<sub>3</sub> every 14 days (7143 IU/day) for a maximum of 2 years to clinically isolated syndrome patients. The D-Lay trial results may provide a clearer picture of the effects of vitamin D<sub>3</sub>, since patients do not have ongoing immunomodulatory treatments, which may confound or bias the results.

## 8. Conclusion

**Summation.** MS has a long history. In 1757, the first reasonably convincing case of MS was reported in the medical literature [1]. In 1960, researchers wrote “... the more sunshine there is in a climate, the less multiple sclerosis there appears to be” [18]. In 2023, we write “vitamin D insufficiency is now believed to contribute causally to MS pathogenesis.” This conclusion is based on compelling evidence gathered from experiments in genetics, biochemistry, immunology, nutrition, and medical science in just the past 5 years. Several research advances stand out. Mendelian randomization studies now confirm genetically determined low serum 25(OH)D as an MS risk factor. Immunological research has highlighted cross-talk between the vitamin D system and the complement regulator CD46 controlling the transdifferentiation of proinflammatory CD4<sup>+</sup> Th1 cells to regulatory CD4<sup>+</sup> Tr1 cells, and the transcription factor FOXP3 controlling the transdifferentiation of proinflammatory CD4<sup>+</sup> Th17 cells to regulatory pCD4<sup>+</sup>Foxp3<sup>+</sup>Treg cells. Both regulatory CD4<sup>+</sup> T cell subsets prevent immune-mediated tissue damage, and both are defective in MS. Biochemical evidence has implicated myeloid lineage cells as the producers of 1,25(OH)<sub>2</sub>D<sub>3</sub> for highly localized signaling to VDR-expressing in the CNS and lymphoid tissues and suggested a model for direct VDR-mediated control of MS-relevant gene transcription. Other biochemical evidence has highlighted cross-talk between the vitamin D system and the MET cycle that supplies single carbon units for epigenetic marking and suggested a model for indirect VDR-mediated control of MS-relevant gene transcription through DNA or histone methylation in OPC differentiation. A transgender study reported the sex hormones modulated MS risk independently of the sex chromosomes and suggested a hypothetical model to explain MS sexual dysmorphisms through 1,25(OH)<sub>2</sub>D<sub>3</sub> and sex hormone interactions in FOXP3 regulation. Now, 265 years after the first probable case of MS was reported, we can describe in some detail a pathway that begins with cutaneous exposure to solar radiation and ends with engagement of the 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR complex with nuclear DNA in several types of MS-relevant cells where it triggers protective mechanisms that together reduce the risk of MS.

**Importance.** MS remains incurable. The global MS disease incidence has increased nearly fivefold in just six decades. MS afflicts nearly 3 million people, most of them women. Many of them are young, productive adults. Scientists have long believed that modifiable environmental risk factors interact with genetic risk factors and sex hormones to cause the demyelination and focal inflammatory responses that are observed in MS. We now know that severe hypovitaminosis D appears to be the strongest modifiable environmental risk factor for MS, with the relative MS risk increasing >10-fold as circulating 25(OH)D levels decline from ~110 to <10 nmol/L (see Fig. 10.4C in Ref. [7]). We have detailed knowledge of genetic risk factors and cells of interest. Oligodendrocytes hold the key to myelination, and CD4<sup>+</sup> T cells hold the key to immunoregulation. We understand the mechanisms of 1,25(OH)<sub>2</sub>D<sub>3</sub> and sex hormone actions, and some target genes have been identified. Two published algorithms predicted MS genetic risk with some success. A report detailing DNA methylation quantitative trait loci in CD4<sup>+</sup> T cells may serve as a guide to find accessible biomarkers of regulatory CD4<sup>+</sup> T cell function in individuals with a predicted high risk of MS. Lastly, we understand how to address nutritional vitamin D insufficiency. Because of these

recent and remarkable scientific advances, the vitamin D and MS research community is poised to modify nutritional vitamin D insufficiency in individuals with a predicted high genetic risk of MS, and quite possibly alter the trajectory to an MS diagnosis. What a remarkable accomplishment that would be.

**Future.** We finished each section of this chapter with open questions for continued research. In Box 101.2, we summarized the knowledge gaps we identified in genetics, immunology, biochemistry, nutrition, and medical science and made a few suggestions for future research. This list of questions and suggestions is not complete, but we hope it will serve as an inducement to advance vitamin D and MS research as rapidly as possible. The results of better-controlled vitamin D<sub>3</sub> intervention trials in individuals with clinically isolated syndrome and hypovitaminosis D, coupled with longitudinal measurement of biomarkers and clinical data, and the deep phenotyping or sequencing analyses of relevant cells donated by participants will very likely increase our insights into mechanisms that apply after the disease process has begun. However, the important long-range goal is MS prevention. Once we understand how to identify individuals at risk of developing MS with precision, and how to modify the strongest of

### BOX 101.2

#### Research challenges from the vitamin D and MS perspective.

##### Challenges in genetics

The MS genetic risk variant-to-function problem remains a major focus. Identifying the downstream transcriptional mechanisms that transduce MS genetic risk and are subject to VDR regulation in MS-relevant cells will be important. A first step will be discovering MS-relevant genes that are differentially expressed in key cells (e.g., monocytes, CD4<sup>+</sup> T cells, or OPC) in the vitamin D–replete and vitamin D–deficient states. A second step will be determining which transcriptional regulatory processes (e.g., chromatin accessibility, epigenetic marking, DNA looping, transcription factor binding, transcription complex recruitment) are influenced either directly or indirectly by the liganded VDR. Also important will be determining how microenvironmental conditions (e.g., sex hormones, inflammatory signals) influence the transcriptional regulatory processes. Of high interest are epigenetic marks in *HLA-DRB1* that have been associated with MS, particularly marks associated with the *DRB1\*1501* risk allele. Would the vitamin D–replete and vitamin D–deficient states influence these epigenetic marks and MS risk gene expression? Also of high interest

are the hormone-responsive enhancers in the *FOXP3* gene that have been associated with extrathymic pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation and function. Could differential 1,25(OH)<sub>2</sub>D<sub>3</sub>, TST, and E2 enhancement of *FOXP3* gene transcription in males and females be a mechanism linking declining 25(OH)D status with increasing MS risk in a female-biased manner?

##### Challenges in biochemistry

In the vitamin D–replete state, activated microglial cells produced 1,25(OH)<sub>2</sub>D<sub>3</sub>, signaling to diverse cells within the CNS to protect this tissue from autoimmune damage. However, it is unclear why vitamin D<sub>3</sub> repletion has not benefitted patients with MS or animals with EAE. Could the rate-limiting 1 $\alpha$ -hydroxylase for 1,25(OH)<sub>2</sub>D<sub>3</sub> biosynthesis be inactivated under inflammatory conditions? For example, if ROS production were to exceed ROS inactivation capacity in the inflamed brain, would ROS-mediated damage irreversibly inactivate the 1 $\alpha$ -hydroxylase?

The ligand-activated VDR enhanced *Blmt* gene expression and the betaine–MET cycle in murine CD4<sup>+</sup> T cells.

*Continued*

### BOX 101.2 (cont'd)

Does this also occur in other cells such as human CD4<sup>+</sup> T cells or OPC? The BHMT enzyme was bound to DNMT3a in the OPC nucleus where the complex enhanced DNA methylation when betaine was added. Does the BHMT–DNMT3a complex enhance DNA methylation in a VDR-dependent manner in OPC? Could this be a repressive epigenetic mechanism controlling expression of the *ID2/ID4* genes in OPC or the *DRB1\*1501* allele in antigen-presenting cells?

#### Challenges in immunology

VDR signaling dampened neuroinflammation, reduced oxidative stress parameters, and increased myelin synthesis through its actions on rodent OPC and pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells. Do these observations apply to human OPC and pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells and to oxidative stress in the human? What CNS tissue homeostatic functions of pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells can be increased by 1,25(OH)<sub>2</sub>D<sub>3</sub>–VDR signals? How do sex hormones influence pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cells? What is the impact of VDR signaling on myelin repair and replacement by either surviving or new OLG in the human? Previous data indicate that *CTLA4* inactivating mutations cause an IPEX-like disease in humans, and new rodent data point to direct VDR-mediated upregulation of CTLA-4 expression in CD4<sup>+</sup> T cells. Do the vitamin D–replete and vitamin D–deficient states influence the expression and/or function of this critically important immune checkpoint molecule in humans?

#### Challenges in nutrition

Serial MRI of RRMS patients revealed a seasonal periodicity with decreases in ambient UV radiation and circulating 25(OH)D preceding changes in new T2 lesion formation by ~2 months. Does this observation apply

only in high-latitude regions, or also in low-latitude regions? Does the patient's age, sex, or vitamin D nutriture (replete vs. insufficient) influence the seasonal periodicity of new T2 lesion formation?

Many studies have reported elevated circulating HCY levels in MS patients, prompting the hypothesis that these patients may have a dysregulated MET cycle, which could affect the cerebral vasculature, redox balance, and epigenetic marking within cells. How common is elevated circulating HCY in MS patients? Would nutritional intervention to correct elevated circulating HCY levels benefit MS patients with this condition? The MS risk in transsexual females was 4.6-fold higher than the risk in transsexual males in a small pilot study. Is this a reproducible finding? Does vitamin D nutriture (replete vs. insufficient) have an influence on MS risk in this population?

#### Challenges in healthcare

Investigators anticipate that the results of ongoing trials with earlier interventions and more robust clinical trial designs may shed light on the actual role of vitamin D<sub>3</sub> supplementation in delaying or preventing an MS diagnosis. Can the harvest of information from clinical trials be improved by longitudinal monitoring of 25(OH)D as well as biomarkers related to CD4<sup>+</sup> Treg cell and CD4<sup>+</sup> Tr1 cell function and MET cycle function?

At least two MS risk prediction algorithms have been published [195,313]. What accessible biomarkers might forecast a prodromal period for MS disease, wherein dysregulated biological processes may be underway but even subtle signs of neurological disability are not yet detectable? Could epigenetic marks in key regions of MS risk genes within MS-relevant cells forecast a dysregulated immune response and suggest new approaches to reduce the risk of an MS diagnosis?

the environmental risk factors, vitamin D insufficiency, we hope millions of people worldwide might be spared an MS diagnosis.

### 9. Summary points

- Observational epidemiology provides strong evidence that low vitamin D status increases the risk of MS and serum 25(OH)D is genetically influenced;
- Mendelian randomization studies confirm genetically determined serum 25(OH)D as one of the causes of MS; the ligand-activated VDR is involved at every step in the epigenetic regulation of genes (e.g., *HLA-DRB1*, *FOXP3*, *IKZF2*, *CTLA4*, *IL10*) with high relevance to MS, from chromatin opening and recruitment of pioneer factors through direct transcriptional regulation.
- New insights into MS etiological mechanisms are derived from analysis of global longitudinal F:M

incidence data, and F:M incidence data in transsexual individuals; the evidence suggests a hormonally triggered and reversible protective mechanism intrinsic to CD4<sup>+</sup> T cells and linked to reproductive success reduces MS risk and severity.

- The 1,25(OH)<sub>2</sub>D<sub>3</sub> and sex hormone–gene interactions apparently converge to enhance *FOXP3* gene expression and protective pCD4<sup>+</sup>Foxp3<sup>+</sup> Treg cell differentiation and function in a sex-biased manner.
- The interplay between VDR–1,25(OH)<sub>2</sub>D<sub>3</sub> and CD4<sup>+</sup> Th1 cells results in amplification of the CD46 costimulatory signals that promote CD4<sup>+</sup> Th1 cell transdifferentiation to the protective IL-10-producing CD4<sup>+</sup> Tr1 cell phenotype; recent data suggest that the CD4<sup>+</sup> Th1 cells from MS patients and COVID-19 patients might be incapable of undergoing this CD46-mediated switch for reasons that are not yet clear, but may reflect low vitamin D status; these data open new avenues of investigation to improve CD4<sup>+</sup> Tr1 cell differentiation and function in MS patients and COVID-19 patients.
- The discovery of 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated enhancement of *Bhmt* gene expression, the methionine cycle, and DNA methylation in CD4<sup>+</sup> T cells, as well as the discovery of BHMT protein bound to DNA methyltransferases and DNA in the OPC nucleus, suggest an epigenetic hypothesis for 1,25(OH)<sub>2</sub>D<sub>3</sub> support of myelin sheath repair and replacement; in this model, 1,25(OH)<sub>2</sub>D<sub>3</sub> enhances the methionine cycle, which facilitates epigenetic silencing of genes encoding transcriptional repressors of OLG differentiation, thereby promoting myelin repair, replacement, and redox balance in the CNS.

# Vitamin D and the epidemiology of multiple sclerosis

*Kassandra L. Munger<sup>1</sup> and Alberto Ascherio<sup>2</sup>*

<sup>1</sup>Department of Nutrition, Harvard TH Chan School of Public Health, Boston, MA, United States <sup>2</sup>Departments of Nutrition and Epidemiology, Harvard TH Chan School of Public Health, Channing Laboratory, Department of Medicine, Brigham and Women's Hospital, and Harvard Medical School, Boston, MA, United States

## OBJECTIVES

- Provide an overview of multiple sclerosis and descriptive epidemiology.
- Discuss MS epidemiology in the context of vitamin D nutrition as a risk factor for MS.
- Present and discuss the literature on vitamin D and MS risk, including studies of sun exposure, dietary vitamin D, and blood 25-hydroxyvitamin D levels.
- Review vitamin D gene-MS association studies.
- Present and discuss the literature on vitamin D and MS disease activity and progression, including observational studies and randomized controlled clinical trials.
- Examine the evidence that vitamin D nutrition is also a risk factor for pediatric onset MS.

## 1. Introduction

Multiple sclerosis (MS) is a disease of the central nervous system (CNS) characterized by an immune system-mediated breakdown of the myelin sheaths that surround the axons of the nerve cells. Two of the major functions of myelin are to facilitate the rapid conduction of nerve cell signals and to protect the axon from damage. In MS, both roles are compromised

and depending on where in the brain or spinal cord these areas of demyelination (lesions) occur, there is a constellation of symptoms that MS patients may experience including optic neuritis, clumsiness, loss of balance, gait ataxia, and paresthesia in the extremities and trunk to name a few [1,2]. Further, many MS patients also have some degree of debilitating nerve pain, fatigue, and cognitive dysfunction, especially as the disease progresses over time [1]. Over 90% of patients show onset with a relapsing-remitting (RRMS) course in which they experience episodes of neurologic deficit (relapses) followed by periods of complete or incomplete recovery (remittance). The clinical diagnosis of MS requires two episodes of neurologic deficit lasting at least 24 h and occurring at least 30 days apart. When only one episode has occurred, the patient is diagnosed with the clinically isolated syndrome (CIS). CIS is typically an early clinical manifestation of MS as approximately 70%–80% of individuals with a CIS will eventually meet the diagnostic criteria for MS [3,4] either by experiencing a second relapse or exhibiting changes in and developments of CNS demyelination or presence of oligoclonal bands in the cerebral spinal fluid [5]. During the early phases of RRMS, there is both clinical and sub-clinical active inflammation and damage occurring in the CNS [6]. Many people with RRMS will enter a secondary progressive phase (SPMS) some decades after initial symptom onset in which they have an accrual of a permanent neurologic deficit as axonal destruction continues. In addition to the physical disabilities, as MS progresses, brain volume decreases and cognitive

function further declines, drastically affecting the quality of life. A small percentage of MS cases ( $\sim 10\%$ ) onset with a primary progressive disease course in which there is an accumulation of physical and cognitive disabilities over time with no clear relapses or remissions. While innovations in disease-modifying therapies have been beneficial in reducing relapse rates and lesion development in early RRMS, most patients will still progress to SPMS. MS remains an incurable progressive disease with an uncertain etiology and contributors to disease activity and progression. There is very strong evidence for a causal role of infection with Epstein–Barr virus (EBV) [7] with risk further modified by genetics (in particular the human-leukocyte antigen (HLA)-DR15\*01 haplotype), cigarette smoking, overweight/obesity in early life, and insufficient vitamin D nutrition [8]. There is also evidence supporting the beneficial role of adequate vitamin D nutrition in MS disease activity and progression. This chapter will discuss the epidemiology of MS with respect to vitamin D and evidence of vitamin D nutrition as a risk factor for developing MS as well as for MS disease activity and progression. A more detailed description of the immunomodulatory effects of vitamin D in MS is provided in Chapter 101.

## 2. Descriptive epidemiology

MS was first formally named and described by Jean-Martin Charcot in the 1860s. He noted that MS typically onsets in young adults between ages 25–30 years and that women were more likely to be affected than men [9]. Over 150 years later both observations persist. MS is the most common non-traumatic neurologically disabling disease in young adults with a peak incidence of onset around 30–35 years of age [10–12], and an estimated prevalence of 1 million in the US and 2.8 million worldwide [13,14]. The overall incidence of MS has been increasing in many countries and an increase among women specifically appears to be driving this trend [15]. In general, women are 2–3 times more likely to develop MS as compared to men [10–12], but studies in several countries have seen a sharp increase in the female to male ratio over the past 50 or so years [16–19]. Studies in the mid-1900s reported lower incidence of MS among non-Hispanic Black (NHB) women and NHB men as compared to non-Hispanic White (NHW) women and NHW men, respectively [20]. However, more recent studies find that MS incidence and prevalence have increased in both NHB women and men and are now more similar to NHWs [21–23]. The reasons behind the increasing female to male sex ratio and increasing incidence in NHB populations are not understood, but changes in various behaviors such as cigarette smoking and sun exposure may play a role [8].

There have been over 200 genes—the majority involved in immune system function—that have been associated with MS though individual gene contributions to risk are small, and having a first-degree relative with MS is one of the strongest risk factors for the disease [24]. The strongest genetic association for MS is the HLA DRB1\*1501 haplotype; carriers have a threefold increased risk of MS [25]. Thus, MS is a multifactorial disease with risk modification occurring in genetically susceptible individuals.

Two observations that strongly suggested that environmental risk factors contribute to MS are 1) the existence of a latitude gradient in MS prevalence [26,27] and 2) the changing MS risk observed with migration [28–30]. Countries farther away from the equator (i.e., at higher latitudes) tend to have a higher prevalence of MS and this prevalence decreases with decreasing latitude (i.e., moving toward the equator). Though an attenuation of the latitude gradient over the last half-century has been observed in the US [22,27], it continues to persist on a global scale [26,31]. Migration studies both within [32] and between countries [33] generally find that groups who migrate to more northern areas have a higher risk of MS than that in the location they migrated from and those who migrate from northern to southern locations have a lower risk than their original location. Younger age at migration may also be an important factor as some studies suggested that migrants less than 15 years old adopted the MS risk associated with their new location while older migrants did not; [28] however, more recent studies support similar change in MS risk even after the age of 15 [30,33,34]. Both the latitude gradient and migration studies support the existence of an environmental risk factor, and these observations are consistent with the role of vitamin D in determining MS risk given the inverse association between vitamin D nutrition and latitude.

## 3. Vitamin D and MS—historical perspective

Vitamin D was first suggested to be a possible risk factor for MS in the 1970's based on the existence of the latitude gradient, the observation that populations which consumed vitamin D-rich foods (e.g., salmon and other fatty fish) had lower incidence rates of MS as compared to populations with diets low in these foods, and inverse correlations between ecologic measures of average annual sunshine and temperature with MS prevalence [35–37]. Though it would be another 30 years before the first epidemiologic studies linked vitamin D nutrition with MS, there were studies in experimental autoimmune encephalomyelitis (EAE), one animal model of MS, showing that mice supplemented with vitamin D [38–40] or exposed to high

UVR [41] were less likely to develop severe EAE or show no symptoms of EAE at all. These observations, coupled with those that vitamin D has immunomodulatory effects [42], prompted the study of vitamin D nutrition as a potentially important factor in MS development.

## 4. Vitamin D and risk of MS

### 4.1 Sun exposure and MS risk

Given both the latitude gradient for MS and that sun exposure is the primary source of vitamin D, time spent exposed to the sun has been studied as both a proxy measure for vitamin D and as a possible exposure having effects independent of vitamin D through other immune modifying pathways [43]. The earliest studies to include an investigation of the association between sun exposure and MS risk were inconsistent with the higher sun exposure-lower MS risk hypothesis. A study with 300 MS cases and 300 controls with sciatica found no difference in the amount of time spent in the summer sun at age 15 [44], and a study in Israel found that MS patients were more likely to report having spent more than 2 hours per day outside during the summer up to age 15 years [45]. Selection bias is the likely explanation for the results in both studies as the controls used were not representative of the source populations for the cases [8]. Since 2000, there have been several case-control studies assessing self-report of sun exposure throughout the life course [46–53]. Though these studies vary in their populations, sample sizes, assessments of past or lifetime sun exposure, and statistical methods, they collectively support that higher sun exposure, in particular during childhood and adolescence, is associated with a reduced risk of MS. While recall bias of self-reported sun exposure behaviors and time in the past is a concern, the studies using actinic damage to the dorsum of the hand—an objective measure of cumulative sun exposure—also find a lower MS risk.

In a study of Australian MS cases and controls [46] increasing actinic damage was inversely associated with MS risk (grade 6 vs. grade 3 OR = 0.17; 95% CI(0.05–0.60)). These findings were confirmed in the larger Ausimmune study (grade 6 vs. grade 2 OR = 0.43; 95%CI(0.21–0.88)) among individuals who had experienced their first demyelinating event [53]. Whether the inverse associations seen in these studies are driven by vitamin D pathways, other sun-induced immune-associated pathways, or both, has been debated [54,55]. Two studies reported that sun exposure and 25(OH)D levels are independent risk factors for MS, suggesting a role for sun exposure in reducing MS risk via non-vitamin D-related mechanisms [53,56]. However, in these studies, vitamin D levels were measured in blood samples taken at the time of the study and not

during the reported time period of sun exposure (in childhood/adolescence) so both associations may still be explained by vitamin D. PhoCIS was an Australian randomized controlled clinical trial of the effects of UVB phototherapy on conversion to MS among patients with a CIS [57]. All participants were also supplemented with vitamin D to raise levels higher than 80 nmol/L. After 12 months, the study found no statistically significant difference in the rate of conversion with phototherapy versus none. One possible explanation is that vitamin D levels were set high via supplementation and further exposure to UVR had no great effect, suggesting that the vitamin D pathway via sun exposure is probably the main mechanism of the effects of sun exposure on MS risk.

### 4.2 Dietary intake of vitamin D and MS risk

Numerous case-control studies have reported that individuals with a high intake of foods or supplements that are rich in vitamin D have a lower risk of MS. Studies in Norway [37], Sweden [58,59], and Australia [60] found a 20%–40% decreased risk of MS among regular consumers of fish and a study on cod liver oil intake during adolescence reported a 30% reduced risk [61]. However, the case-control study design is not optimal for assessing diet-disease associations as they are particularly prone to selection and recall biases [62]. Further, foods that are rich in vitamin D tend to also be rich in other nutrients which may have a role in MS development including polyunsaturated fatty acids [63,64] and vitamin A [65].

Longitudinal prospective studies of diet and disease are much less likely to be biased by selection or recall and they are the preferred observational study design for assessing associations between diet and disease [66]. In the Nurses' Health Study (NHS) and NHS II, two longitudinal cohorts of over 200,000 women, dietary intake are assessed every 4 years using extensively validated food frequency questionnaires [67]. The dietary foods and nutrients used in a prospective analysis are those collected before the woman develops the disease of interest. In the NHS and NHSII, pre-diagnostic dietary intake of >400 IU/day of vitamin D as multivitamin supplements was associated with a 40% decreased risk of MS when compared to women who did not use multivitamin supplements [68]. However, as with the case-control studies, other nutrients in the multivitamins may be confounding the association. Another important consideration is that the contribution of dietary vitamin D (including supplements) to overall vitamin D status is less than vitamin D derived from sun exposure. While the studies of dietary vitamin D via food and supplements support the hypothesis, they provide weak evidence of a potential protective effect of adequate vitamin D nutrition on MS risk.

### 4.3 25-Hydroxyvitamin D (25[OH]D) and MS risk

The limitations of dietary vitamin D intake and sun exposure as proxies for complete vitamin D nutrition allow only for indirect evidence that vitamin D specifically is driving the decreases in MS risk observed. Circulating blood levels of 25-hydroxyvitamin D (25(OH)D) are an integrated measure of vitamin D from both diet and sun exposure and provide a more direct assessment of vitamin D nutrition. Studies have found low 25(OH)D levels in persons with MS [69]. However, reverse causation is a plausible explanation of the results as blood samples are taken after the onset or diagnosis of MS or CIS (CIS—very early MS) has been made and the MS disease process or behavior changes in persons with MS, such as sun avoidance, may be the reason for the lower vitamin D levels observed.

To address this limitation, prospective nested case-control studies measuring circulating levels of 25(OH)D in healthy individuals and following them for an MS diagnosis have been conducted in four well-defined populations, and all are consistent with sufficient 25(OH)D levels associated with a decreased risk of MS [70–73] (Fig. 102.1). A study among active-duty US military personnel [70] documented 257 MS cases and matched them to 514 controls on age, sex, race, dates of sample collection, and branch of military service. For each case and control, up to three serum samples collected before the date of MS symptom onset (index date in controls) were obtained from the Department

of Defense Serum Repository, which stores over 65 million serum samples from over 10 million personnel collected periodically over the course of their military careers. There was a median time of 4 years between sample collection and MS onset. Among NHW personnel, pre-symptom 25(OH)D levels  $>100$  nmol/L was associated with a 50% decreased risk of MS. This association was not seen among NHB or Hispanics, but this may be due to smaller sample sizes and a limited range of 25(OH)D levels in these groups.

There have been two studies from Sweden utilizing various biobanks in the country. The first used serum samples stored by the North Sweden Maternity Cohort and the North Sweden Health and Disease Study [71]; 192 MS cases and 384 controls matched on sex, biobank, sampling date, and age had a serum sample stored that was collected prior to the date of MS onset (index date in controls) with the samples collected a median of 9 years before the onset of MS. Levels of 25(OH)D  $>75$  nmol/L were associated with a 60% reduced MS risk. The second study was conducted using five Swedish university hospital biobanks and one public health biobank; [73] 665 MS cases and 655 controls matched on biobank, sex, date of sample collection, and age had samples collected a median of 8 years before onset. Sufficient 25(OH)D levels ( $\sim >70$  nmol/L) were associated with a 32% decreased MS risk.

The studies in the United States and Sweden all support that adequate vitamin D nutrition in otherwise healthy young adults is associated with a decreased risk of MS. A study in the Finnish Maternity Cohort

FIGURE 102.1 Main results from the prospective studies of 25(OH)D and MS risk.

(FMC) examined whether vitamin D insufficiency ( $<50$  nmol/L) or deficiency ( $<30$  nmol/L) was associated with an increased risk of MS [72]. In the previous studies, too few individuals had low enough 25(OH)D levels to study this end of the range. The FMC has collected and stored serum samples obtained during the first trimester of  $>98\%$  of all pregnancies in Finland since 1983 [74]. Linking the FMC to hospital and prescription registries, 1092 women with MS had at least one sample stored in the FMC that was collected prior to the symptom onset of MS. They were matched to 2123 controls on birthdate and area of residence, and the mean time between sample collection and MS onset was 9 years. Over 50% of the women had 25(OH)D levels in the deficient range and both deficient and insufficient levels of 25(OH)D were associated with a twofold increased risk of MS.

As mentioned above, these studies are not subject to recall bias and selection bias is minimized by the nested case-control study design. However, confounding and reverse causation as explanations for the findings need to be considered. The time lag between pathological onset and MS symptom onset is referred to as the “prodromal phase” of MS [75]. Various studies have estimated this phase may begin 5–10 years before classic MS symptoms appear, implying that in the prospective studies, there are likely some 25(OH)D levels that are being measured within this time frame and the 25(OH)D levels may be affected by the subclinical disease process. Studies of early life 25(OH)D exposure and future risk of MS may help to clarify given the long lag time between early life exposure and adult-onset MS.

Ueda et al. [76] conducted a case-control study in Sweden of 459 MS cases and 663 controls who had neonatal dried blood spots (DBS) stored since their birth in 1975 or later in the Swedish Phenylketonuria Register. They measured 25(OH)D levels in the DBS and found no association between neonatal 25(OH)D levels and future risk of MS. Several limitations of the study, such as degradation of some DBS sampled and low control participation leading to a distortion of the true 25(OH)D exposure distribution of the source population, may have contributed to a lack of association in this study [77].

There have been two prospective nested case-control studies on early life exposure to 25(OH)D and the risk of MS in adulthood. One was conducted in the FMC using samples collected during the pregnancy with the offspring who later developed MS [77] and the other in the Danish MS registry among individuals with stored neonatal dried blood spots [78]. Both studies found a 1.5- to twofold increased risk of adult-onset MS among offspring with evidence of exposure to 25(OH)D levels  $<30$  nmol/L during gestation. These studies suggest that vitamin D nutrition in early life is

also important for the risk of future MS and that the observed associations between 25(OH)D in young adulthood and MS in prospective studies may not be entirely explained by reverse causation.

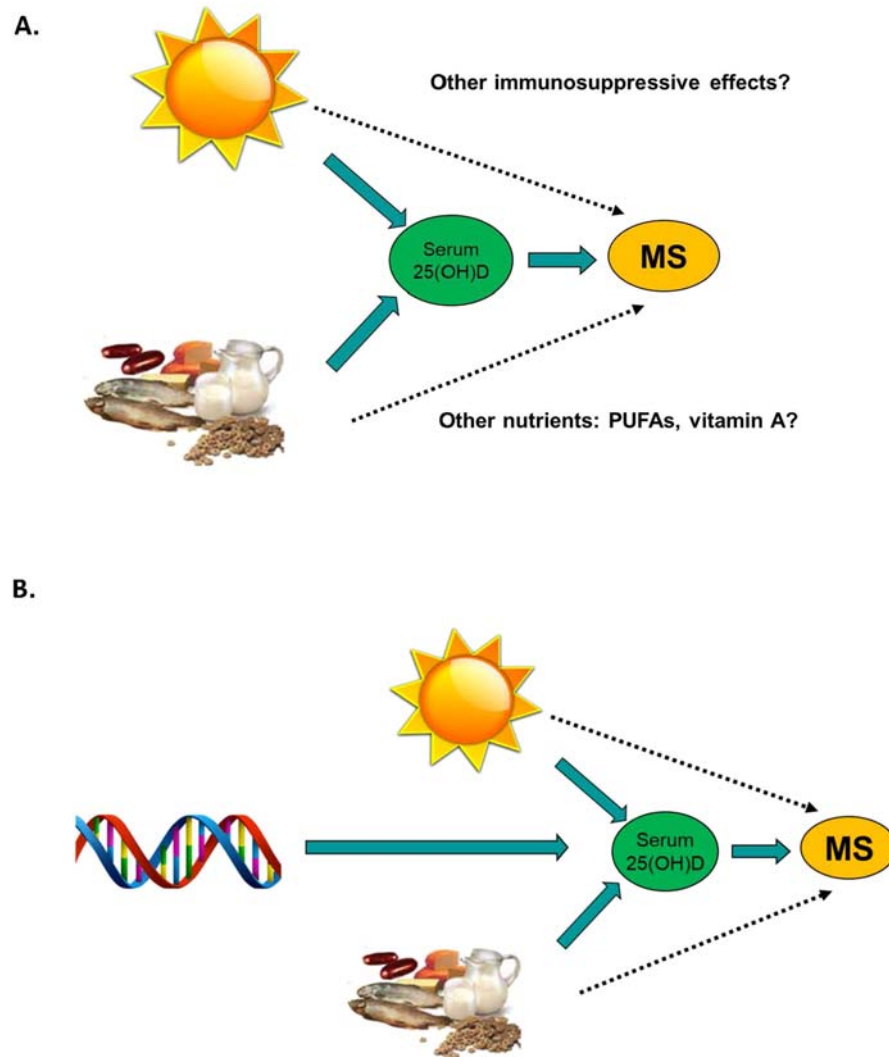

Confounding of the 25(OH)D—MS association by sun exposure via non-vitamin D pathways or other nutrients in vitamin D-rich foods, such as polyunsaturated fatty acids, is plausible (Fig. 102.2). Mendelian randomization (MR) studies minimize confounding as an explanation of observed associations by taking advantage of the fact that genes are randomly distributed before any confounding exposures occur. The sorting of gene variants that contribute to determining 25(OH)D levels are therefore not associated with sun exposure or diet and cannot confound the 25(OH)D—MS risk association. Six MR studies have been conducted and all have found an association between higher genetically determined 25(OH)D levels and lower MS risk [79–84] suggesting that confounding cannot completely explain the 25(OH)D and MS risk association in the prospective nested case-control studies. Importantly, however, MR studies also do not prove there is a causal association and they are limited by untestable or unprovable assumptions [85]. However, multiple studies in different populations with similar results suggest these assumptions are met or have minimal impact. More details of these studies are provided below and in Table 102.1.

#### 4.4 Vitamin D genes and MS risk

Several genes related to vitamin D metabolism and action have been assessed with respect to MS risk including *DHCR-7*, *VDBP*, *VDR*, *CYP27B1*, and *CYP24A1*. Results of these candidate gene studies have been mixed and there are no unequivocal associations between polymorphisms in these genes and MS risk. MR studies, however, create instrumental variables using gene variant predictors of 25(OH)D levels from large genome-wide association study (GWAS) and assess whether there are associations between genetically determined levels of 25(OH)D and MS risk. These results have been consistent in showing that genetically determined higher levels of 25(OH)D are associated with lower MS risk. A more detailed description of MR and studies of vitamin D and human health is provided in Chapter 61, but a summary of the key genes linked to vitamin D and MS is shown below.

##### 4.4.1 *NADSYN1/DHCR-7*

The *NADSYN/DHCR-7* locus on chromosome 11 has been associated with vitamin D levels in GWAS [86,87]. The *DHCR-7* gene encodes the enzyme 7-dehydrocholesterol reductase which converts 7-dehydrocholesterol to cholesterol. 7-dehydrocholesterol is also the precursor

**FIGURE 102.2** (A) Schematic of potential confounding of the association between 25(OH)D and MS risk by other immunosuppressive actions of UVR exposure and other nutrients found in foods with vitamin D. (B) Schematic of the Mendelian randomization studies. Using genes that predict 25(OH)D levels as instrument variables eliminate confounding by other properties of UVR or dietary intake of vitamin D.

to vitamin D produced via UVB exposure. High levels of 7-dehydrocholesterol reductase may result in low vitamin D levels as 7-dehydrocholesterol is preferentially converted to cholesterol. Results of the few studies conducted suggest that there is no association between SNPs in this locus and MS risk [88–90].

#### 4.4.2 *CYP2R1*

The *CYP2R1* gene, also located on chromosome 11, encodes the 25-hydroxylase enzyme which converts vitamin D to 25(OH)D in the liver. Two studies have found an increased MS risk associated with SNP rs10766197 in Italian [89] and Spanish [91] populations. The rs117913124 SNP was associated with an increased MS risk in a White European population [92]. No associations between other SNPs in *CYP2R1* and MS risk have been observed [88,89,93].

#### 4.4.3 *CYP27B1*

The *CYP27B1* gene encodes the  $1\alpha$ -hydroxylase enzyme that converts 25(OH)D to the biologically active 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ). A 2009 GWAS by the Australia and New Zealand Multiple Sclerosis Genetics Consortium (ANZgene) first identified three SNPs on chromosome 12q13-14 associated with MS risk: rs703842, rs10876994, and rs1236853 [94]. In a 2011 GWAS, the International Multiple Sclerosis Genetics Consortium (IMSGC) also reported an association with rs1236853, but not rs703842 or rs10876994 [24]. A non-GWAS study among Han Chinese also found an association between rs1236853 and MS risk [95]. Other studies including the rare *CYP27B1* variants rs118204009, rs118204011, rs118204012, rs12368653, and rs10876994 have produced mixed results and no clear consistent associations with MS risk [91,96–101]. In

**TABLE 102.1** Overview of Mendelian randomization studies of genetically determined 25(OH)D levels and risk of MS.

Study	25(OH)D GWAS (n, population)	MS population	25(OH)D gene-related SNPs included	MR OR (95% CI), <i>P</i> value
Mokry et al. [79]	SUNLIGHT (n = 33,996, European)	IMSGC (n = 14,498 MS/24,091 controls)	rs2282679, rs12785878, rs10741657, rs6013897	2.0 (1.7–2.5) $P = 7.7 \times 10^{-1}$ for a 1 SD decrease in 25(OH)D levels
Rhead et al. [80]	Genetic risk score from three previously published SNPs	KPNC (US) and EIMS/GEMS (Sweden) (Total n = 7391 MS/14,777 controls)	rs2282679, rs2060793, rs3829251	0.85 (0.76–0.98) $P = .003$ for each increase in number of alleles associated with higher 25(OH)D levels.
Gianfrancesco et al. [81]	Genetic risk score from three previously published SNPs	US (n = 394 pediatric-onset MS/10,875 controls) and Sweden (175 pediatric-onset MS cases and 5736 controls).	rs2282679, rs2060793, rs3829251	0.72 (0.55–0.94) $P = .02$ for each increase in the number of alleles associated with higher 25(OH)D levels.
Jacobs et al. [82]	SUNLIGHT (n = 79,366, European)	IMSGC (n = 14,802 MS, 26,703 controls)	rs8018720, rs3755967, rs79798805, rs12785878, rs107416557, rs17216707	0.57 (0.41–0.81), $P = .001$ for a 1 SD decrease in 25(OH)D levels
Harroud et al. [84]	UK biobank (n = 401,460 British)	IMSGC (n = 14,802 MS, 26,703 controls)	88 SNPs	0.72 (0.60–0.87) $P = 6.2 \times 10^{-4}$ for a 1 SD increase in 25(OH)D
Wang [83]	UK biobank (n = 401,460 British)	IMSGC (n = 14,498 MS, 24,091 controls)	20 SNPs	

*CI*, confidence interval; *EIMS/GEMS*, Epidemiologic Investigation of Multiple Sclerosis/Genes and Environment in Multiple Sclerosis; *GWAS*, Genome-wide association study; *IMSGC*, International Multiple Sclerosis Genetics Consortium; *KPNC*, Kaiser Permanente Northern California; *OR*, odds ratio; *SD*, standard deviation; *SNPs*, single nucleotide polymorphism.

contrast, studies of the rs703842 SNP (C vs. T) in the 3' UTR have shown a consistent inverse association with MS risk [93,95,96,102–106], and a meta-analysis of the pre-2019 studies reported an odds ratio = 0.85, 95%CI: 0.80–0.89 for MS risk associated with carrying the “C” allele [107].

#### 4.4.4 DBP

As a major determinate of vitamin D levels, variants of the vitamin D binding protein (DBP, also known as Group-specific component or Gc) have been studied with respect to MS risk. Two SNPs in exon 11, rs7041 and rs4588, lead to variation in the DBP such that there are three main DBP haplotypes: Gc1f, Gc1s, and Gc2. Gc1f is associated with higher 25(OH)D levels and is more common in Blacks than Whites, Gc1s is associated with lower 25(OH)D levels and occurs more frequently in Whites than Blacks [108]. Two studies of the Gc alleles in 1988 found no association between them and MS risk [109,110]. Subsequent studies also failed to find any associations between rs7041 and rs4588 and the risk of MS [99,103,104,111,112].

#### 4.4.5 CYP24A1

The *CYP24A1* gene encodes the 24-hydroxylase, the enzyme that deactivates 25(OH)D and 1,25(OH)<sub>2</sub>D by adding a hydroxyl group to carbon 24. In the ANZgene GWAS [94], SNPs on chromosome 20q13 were associated with MS risk. Though there are other candidate genes in the region (e.g., CD40), *CYP24A1* also maps to this location. In the IMSCG GWAS [24], rs2248359 on chromosome 20 was significantly associated with MS risk and mapped to *CYP24A1*, suggesting that the identification of 20q13 as a locus of interest in the ANZgene study may have been picking up an association with *CYP24A1*. The rs2248359 SNP is in the promoter region of *CYP24A1* and regulates the expression of the gene. However, a candidate gene study conducted in a Han Chinese population found no association between this promoter SNP and MS risk [95]. A study of the rs2296241 SNP found no association with MS risk [93], but an Italian study reported an increased risk of MS with homozygosity of the minor allele “C” in rs22481837 [113], which is associated with low 25(OH)D levels. A transmission disequilibrium analysis of 16 *CYP24A1* SNPs found no evidence of MS risk associated with these SNPs in a Canadian population of MS cases and first-degree relatives [103].

#### 4.4.6 VDR

The vitamin D receptor gene, *VDR*, is of particular interest with respect to MS risk as it is a nuclear receptor that binds vitamin D response elements in DNA thereby regulating the expression of genes in a variety of cell types, including those of the immune system. There

are four restriction fragment length polymorphisms: *ApaI* (rs7975232), *BsmI* (rs1544410), *FokI* (rs2228570), and *TaqI* (rs731236). While the *VDR* is the most studied vitamin D-related gene with MS risk, studies have generated mixed results on the associations between these RFLP and MS risk [93,114–140]. These differences are likely due to combinations of small sample sizes in the case-control studies, low power, and the race, ethnicity, or location of the population included. There have been several meta-analyses of the studies on *VDR* RFLPs and MS risk published since 2011 [123,140–143]. In two from 2019, one included 27 studies [142] and one 30 studies [143]. For the RFLP *ApaI*, both meta-analyses reported no statistically significant associations with MS risk in White populations, but in Asians, a reduced MS risk with having *ApaI* was seen. In Zhang et al.'s analysis, there was no association between the RFLP *BsmI* either overall or in population subgroups, whereas Imani et al. reported no association in Whites, Asians had a statistically significant 78% increase in MS risk if they carried two *BsmI* variants. The reasons for this difference are not clear but may be due to one meta-analysis having included three studies the other did not, as well as differing interpretations or errors of the original data. The *TaqI* RFLP was significantly associated with a lower MS risk in White populations and no associations were found in Asians. The *FokI* RFLP was inversely associated with MS in both White and Asian populations in one meta-analysis [142], but not the other [143].

#### 4.4.7 Mendelian randomization (MR) studies

As discussed above, the MR studies of 25(OH)D and MS risk lend support for the causality of the observational study findings that high levels of 25(OH)D are associated with a reduced risk of MS as they minimize both confounding and reverse causation (see Chapter 61). Additionally, the MR studies support the role of genetic variants in vitamin D metabolism-associated genes. Where the results of candidate gene case-control studies described above have been largely equivocal, the inverse associations between genetically determined 25(OH)D levels and MS risk reported in the 6 MR studies conducted to date provide strong evidence that vitamin D-related genes impact MS risk.

The salient features of the 6 MR studies that have been conducted are shown in Table 102.1. Four [79,82–84] of the six studies used large 25(OH)D GWAS—SUNLIGHT and UK Biobank—for discovery and the IMSCG to test the association between the 25(OH)D level associated SNPs and MS risk. Two studies utilizing data from the US and Sweden [80,81] created a genetic risk score based on three SNPs known to affect 25(OH)D levels and reported a decreased risk of MS with an increasing number of alleles associated with

higher 25(OH)D levels in both adult- [80] and pediatric-onset [81] MS. Collectively, the MR studies strongly support a role for vitamin D in MS development. However, all of these studies were conducted in largely White, European populations, so whether these results extend to other races and ethnicities requires study. Further, they do not inform at what stage of life higher 25(OH)D levels may be important for determining MS risk or whether 25(OH)D levels affect MS outcomes.

## 5. Vitamin D, race, and MS risk

The vast majority of all the research described above has been conducted in largely White populations of European descent. In the prospective nested case-control study of 25(OH)D and MS risk in the US military the distribution of 25(OH)D was too narrow and the sample size among Blacks with MS too small to evaluate the risk of MS with vitamin D in this group. As described elsewhere in detail, endogenous production of vitamin D with exposure to UVB is inversely proportional to the amount of melanin pigmentation in the skin; therefore, Blacks, especially those living in more northern latitudes, have a high risk of vitamin D deficiency [144]. Studies among Kaiser Permanente members in Southern California [56] reported that levels of 25(OH)D in one sample collected after MS onset were not associated with MS risk in Blacks, but they were inversely associated with MS in Whites. Further, a lifetime history of sun exposure was associated with a reduced risk of MS in both Blacks and Whites. The authors concluded these results were more consistent with non-vitamin D pathways of UVB exposure being more relevant to MS risk than vitamin D itself. However, an assessment of lifetime exposure to the sun is a better measure of overall vitamin D status than one measure taken in adulthood and the results are also consistent with an inverse association of vitamin D with MS risk in Blacks. Much more research on vitamin D as a risk factor for MS in non-White populations is needed [144].

## 6. Vitamin D and MS disease activity and progression

Despite effective therapies that reduce relapse rates and the development of new lesions, the progression of relapsing-remitting MS to secondary progressive MS occurs in most cases. As such, whether adequate vitamin D nutrition may favorably modify MS activity or progression is an active area of research. MS “activity” refers to more acute manifestations of the illness such as conversion from a CIS to definite MS, rate of relapse

**TABLE 102.2** Expanded disability status scale (EDSS) for multiple sclerosis (see Ref. [145] for more detail).

- 
- 0 = Normal
  - 1–1.5 = No disability, but some abnormal neurological signs
  - 2–2.5 = minimal disability
  - 3–4.5 = Moderate disability, affecting daily activities, but you can still walk
  - 5–8 = more severe disability, impairing your daily activities and requiring assistance with walking
  - 8.5–9.5 = very severe disability, restricting you to bed
  - 10 = Death
- 

occurrence, and the appearance of new demyelinating lesions in the CNS visible on magnetic resonance imaging (MRI). MS progression is a more chronic phase of the disease and is caused by the accumulation of neurological deficit that is typically measured by the sustained increase (usually at least 6 months) of disability on the Expanded Disability Status Scale (EDSS) [145] (Table 102.2).

Other measures such as brain atrophy and cognitive function also provide insight into MS progression. There have been both observational studies and randomized clinical controlled trials on vitamin D and MS outcomes. Common criticisms of the observational studies include confounding and reverse causation biases and as a result cannot show that vitamin D has a direct effect on clinical or MRI outcomes. The RCTs also pose challenges to interpretation primarily given their heterogeneity in the vitamin D intervention employed and disease-modifying therapies the participants use, sample size (and thus power), and follow-up time to observe MS outcomes which vary from as little as 6 up to 22 months (Table 102.3). Interpretation and comparison of the results from both study designs must be within the context of these main limitations.

### 6.1 Conversion from CIS to MS

#### 6.1.1 Observational studies

Several studies have shown that insufficient or deficient 25(OH)D levels are associated with a higher rate of conversion from a CIS to clinically definite MS (CDMS) [156–158]. In an Italian study [156], 100 patients with CIS were followed for a median of 7 years and levels of 25(OH)D 32.7 nmol/L were associated with a 2–3fold increased risk of conversion to CDMS as compared to CIS patients with 25(OH)D levels between >32.7 and <71.6 nmol/L. Similarly, a European study of 1047 CIS patients followed for a median of 4 years found that those who were in the bottom quartile of 25(OH)D

**TABLE 102.3** Randomized controlled clinical trials of vitamin D and MS outcomes.

Author, year	n	Duration	Vitamin D intervention	25(OH)D level (nmol/L) at end of study treated versus placebo <sup>a</sup>	Main results
Burton (2010) [146], Kimball (2011) [147]	49	12 months	Cholecalciferol increased from 4000 IU/day to 40,000 IU/day over 28 weeks, followed by a reduction to 10,000 IU/day for 12 weeks and to 4000 IU/day for 6 weeks Calcium: 1200 mg/day; placebo: Up to 4000 IU vitamin D/day and calcium	200 versus not reported	In treated versus non-treated, nonsignificant reduction in annualized relapse rate (0.26 vs. 0.45) and proportion of patients experiencing a relapse (0.16 vs. 0.37); suggestion of lower EDSS at EOS for vitamin D group (1.15 vs. 1.45)
Soilu-Hänninen (2012) [148]	66	12 months	Cholecalciferol 20,000 IU/wk all using IFNB-1b	110 versus 50	Nonsignificant reduction MRI T2 burden of disease ( $P = .1$ ); number of T1 Gd enhancing lesions significantly decreased ( $P = .004$ ). Nonsig. Favorable effects on EDSS ( $P = .07$ ) and timed tandem walk ( $P = .07$ ).
Kampman (2012) [149]	68	22 months	Cholecalciferol 20,000 IU/wk. Treated and placebo groups were given 500 mg calcium and all allowed to continue routine vitamin D supp.	123 versus 62	No difference in relapse rate, EDSS, or MSFC changes
Stein (2011) [150]	23	6 months	Ergocalciferol 6000 IU/d placebo: 1000 IU/d	6000 IU/d: 120 (median) 1000 IU/d: 69	Increase in EDSS and relapses in high-dose vit D group
Mosayebi (2011) [151]	62	6 months	Cholecalciferol 300,000 IU/month all using IFNB-1a	~140 versus ~25	No difference in EDSS or number of Gd-enhancing lesions
O'Connell (2017) [152]	29 CIS	24 weeks	Cholecalciferol 5000 IU/d or 10,000 IU/d	5000 IU/d: 129 10,000 IU/d: 168 Placebo: 71	No difference in any clinical or imaging outcomes
Hupperts (2019) [153]	229	48 weeks	Cholecalciferol 6670 IU/d 1st 4 wks, 14,007 IU/d 44 wks. All participants using IFNB-1a	216 versus 50 (median)	No difference in NEDA-3 at wk 48 (36.5% vs. 35.3%). Lower rate of combined unique activity lesions (IRR = 0.68, $P = .005$ ) and decrease in T2 lesions volume ( $P = .04$ ) in vitamin D group
Camu (2019) [154]	129	96 weeks	Cholecalciferol 100,000 IU every other week. All using IFNB-1a	157 versus 57	ITT: no association with annualized relapse rates. In completers: Decreases were observed for relapse rate, new T1 lesions, and T1 lesion volume
Dörr (2020) [155]	53	18 months	Cholecalciferol every other day 20,400 versus 400 IU. All using IFNB-1b	20,400 IU: 162 400 IU: 56	No associations with any clinical or imaging outcomes

<sup>a</sup>mean level unless otherwise noted.

had a faster rate of conversion to CDMS as compared to those with higher vitamin D levels [157]. A study within the BENEFIT trial of early versus late administration

interferon- $\beta$ 1b among 465 CIS patients found that those with an average of 25(OH)D levels <50 nmol/L over the first year of the trial had a higher probability of CDMS

over years 2-5 of the trial [158]. CDMS is diagnosed in CIS patients after they experience a second clinical attack (relapse) of neurologic deficit lasting for at least 24 h in the absence of fever or infection [5]. The inverse associations between 25(OH)D levels and progression from CIS to CDMS suggest that 25(OH)D may also have a beneficial effect on relapse rate among persons with MS.

### 6.1.2 Randomized control trials (RCT)

There has only been one trial of vitamin D in persons with a CIS [152]. Participants were randomized to either receive cholecalciferol 5000 IU/d, 10,000 IU/d, or placebo. Over the 24 weeks of the study, there was no difference on clinical or imaging outcomes between these groups. However, the short duration and small sample size ( $n = 29$ ) may in part explain the null results.

## 6.2 Relapse rates

### 6.2.1 Observational studies

In general, persons with MS tend to avoid prolonged sun exposure as the heat can exacerbate their symptoms, which in turn can lead to vitamin D deficiency or insufficiency in MS patients. Several studies have found that low blood 25(OH)D levels are predictive of an increase in MS relapse rate [159–164]. One important caveat of these studies, however, is that reverse causation may explain the results—that is, persons with MS and high vitamin D levels may have less active disease and are able to tolerate sun exposure or actively take a vitamin D supplement. A study among individuals with a CIS in the BENEFIT trial minimized this limitation by using average 25(OH)D levels in the first year of the trial as a predictor of relapse rate in years two through five; average 25(OH)D levels  $\geq 50$  nmol/L were associated with a 57% decrease in risk of annualized relapses during the follow-up [158]. However, no association was seen between 25(OH)D levels and annualized relapse rate among RRMS participants in the BEYOND trial [165]. Possible explanations for the seemingly conflicting result include that participants in BEYOND had established MS with a median time since onset of 3 years (range  $<1$  to  $>10$  years) at baseline and that the follow-up was only to year two of the trial as compared to year five in BENEFIT.

### 6.2.2 RCTs

Overall, RCTs have not found an association between vitamin D supplementation and reduced annualized relapse rates (Table 102.3). Some explanations for the inconsistency with the observational studies include a shorter duration of follow-up and low statistical power to detect an association.

## 6.3 Expanded Disability Status Scale (EDSS)

### 6.3.1 Observational studies

The Expanded Disability Status Scale (EDSS) is a commonly used measure of disability progression in MS studies. A brief summary of the EDSS is shown in Table 102.1, and Kurtzke [145] provides a detailed and in-depth definition of each step (0 and half-steps from 1–10). A patient's EDSS is assessed by a neurologist or MS specialist, and the lower the score, the lower the disability experienced by the patient at that point in time. Most of the cross-sectional studies that measure 25(OH)D levels at the same time as the EDSS have found an inverse association between them [164,166–169]. However, whether this inverse association reflects 25(OH)D as a risk factor for EDSS progression or if the greater disability leads to less time outdoors or in the sun resulting in lower 25(OH)D levels cannot be determined from these studies. In prospective studies where 25(OH)D is measured as a predictor of future EDSS results has been mixed. In the BENEFIT study [158], higher average 25(OH)D levels in year 1 were associated with less progression on the EDSS in years 2–5. In the BEYOND study [165], there was a non-statistically significant lower risk of EDSS progression among those with higher 25(OH)D levels over a median of 2 years of follow-up.

### 6.3.2 RCTs

No associations between vitamin D supplementation and EDSS were reported, with the exception of the RCT by Stein et al. [150] (Table 102.3). However, several limitations to this trial, including imbalances between the treated (high dose) and nontreated (low dose) groups in age and sex were not accounted for in the analyses.

## 6.4 MRI

### 6.4.1 Observational studies

Favorable MRI outcomes, including fewer number of new or active CNS lesions and lower lesion volume among CIS or RRMS patients with higher levels of 25(OH)D have been observed [158,163,165,170] (Table 102.4). While the magnitudes of the relative risks are for a range of 25(OH)D increments across studies, there is convergence in that as 25(OH)D levels increase, the risk of developing new T2 Lesions, new gadolinium-enhancing (active) lesions and a cumulative number of active lesions among MS patients decreases. Studies have also assessed whether 25(OH)D levels predict T2 lesion volume or brain volume loss. Ascherio et al. [158] reported that participants in the BENEFIT trial with an average 25(OH)D in the first year  $\geq 50$  nmol/L had a 9% reduction in T2 lesions volume between years

**TABLE 102.4** Summary of 25(OH)D levels and MRI outcomes in CIS/RRMS patients—prospective studies.

Author, year	n	Duration	25 (OH) D unit	New T2 lesions	New active (Gd +) lesions	Cumulative # new active lesions
Mowry (2012) [163]	469	1 year	25 nmol/L increase	RR = 0.85 (0.76–0.95), P = .004	RR = 0.68 (0.53–0.87), P = .002	NA
LøkenAmsrud (2012) [170]	88	6 months	10 nmol/L increase	RR = 0.88 (0.78–1.0), P = .04	RR = 0.87 (0.77–0.99), P = .04	NA
Ascherio (2014) [158]	464	48 months	> = 50 nmol/L versus <50 nmol/L	NA	RR = 0.43 (0.26–0.70), P = <0.001 per 50 nmol/L increase	RR = 0.73 (0.60–0.89), P = .002
Fitzgerald (2015) [165]	1482	24 months	50 nmol/L increase	NA	NA	RR = 0.69 (0.55–0.86), P = .001

two and five and a 0.34% lower yearly loss in brain volume over the same time, as compared to those participants with 25(OH)D levels <50 nmol/L. In the BEYOND trial, no association between 25(OH)D levels and brain volume was observed but the follow-up of 2 years may have been too short to see any meaningful changes [165].

Several of the RCTs found evidence in support of vitamin D supplementation and beneficial effects on MRI outcomes including reduction in CNS lesion burden and lesion volume (Table 102.3), though most were underpowered to detect statistically significant differences between the groups. While two recent trials, SOLAR [153] and CHOLINE [154], did not meet their primary outcomes, both suggested that lower CNS lesion burden was achieved in the high-dose vitamin D groups as compared to placebo (Table 102.3).

Collectively, the strongest evidence from the observational and RCT studies is that vitamin D has beneficial effects on CNS lesion development and volume both early in the disease process as well as in RRMS patients with established disease. The demyelinated areas of the CNS are indicative of an underlying immune and inflammatory process that drives the destruction of the myelin sheaths and axons of the nerve cells. The convergence of the prospective observational and RCT findings on MRI outcomes suggests that vitamin D likely has a role in affecting this immune and inflammatory response.

## 7. Pediatric onset MS

An estimated 3%–10% of all MS cases experienced symptoms prior to age 18 and have pediatric-onset MS [171]. As with adult-onset MS, pediatric-onset MS is also associated with the HLA-DRB1\*1501 risk allele [172], infection with EBV [172], and being obese/overweight in childhood [173,174]. Vitamin D as a risk factor and modifier of disease activity has also been studied in

this population, though not as extensively as in the adult-onset population. Reasons for this may include the smaller population or no pre-onset blood samples available to conduct prospective studies.

Abundant sun exposure in childhood and adolescence has been associated with a lower risk of adult-onset MS as described above. However, there have been no studies looking at the link between sun exposure and pediatric MS onset. A study in Canada [172] included 302 children with an incident demyelinating event for a median of 3 years. Blood levels of 25(OH)D were measured in samples collected within 40 days of the onsetting event. Over the course of the follow-up, 21% of the children were diagnosed with MS and risk was increased among those with lower 25(OH)D levels (per 10 nmol/L decrease in 25(OH)D: HR = 1.11, 95% CI: 1.00–1.25). A MR study of vitamin D and pediatric MS risk found that genetically determined higher 25(OH)D levels were associated with a 28% decreased risk [81].

Three studies have suggested that higher 25(OH)D levels are associated with a lower relapse rate in pediatric MS. Mowry et al. [175] reported that in 110 children with MS or CIS followed for a median of 1.7 years from blood collection that every 10 ng/mL increase in 25(OH)D was associated with a 34% reduced relapse rate. A study in 181 pediatric MS and CIS cases suggested that the association between vitamin D and relapse rate may be modified by HLA-DRB1 alleles as a reduced relapse rate with increasing 25(OH)D was only seen among carriers of HLA-DRB1\*1501 or \*1503. There is also evidence suggesting that having genetically lower 25(OH)D is also associated with a twofold increase in relapse rate in pediatric MS [176].

The current evidence does support a role for vitamin D nutrition in both risk of pediatric-onset MS as well as in relapse occurrence among children with MS. Further studies confirming these findings as well as researching how race/ethnicity, sex, or other MS risk factors may

modify these associations are warranted. Observational or RCT studies on vitamin D supplementation and other MS outcomes also need to be considered.

## 8. Conclusion

There is strong evidence supporting vitamin D nutrition as a risk factor for MS, as well as vitamin D having beneficial effects on MS disease activity and progression, but many questions remain. Associations between the level of prenatal vitamin D exposure, sun exposure in childhood and adolescence, and 25(OH)D levels in young adulthood suggest that vitamin D levels in early life are important in determining MS risk, but is one life stage a more critical period than another? The feasibility of conducting an RCT of vitamin D and primary prevention of MS has been debated. Some of the challenges to design include whether an RCT should be in the general population or only among first-degree relatives of persons with MS, which begs the question of whether it is ethical to withhold high vitamin D doses from first-degree relatives given the observational data. What doses of vitamin D should be tested? Given MS is a rare disease, even among first-degree relatives, an RCT would require a large sample size and a long duration of follow-up, especially if early-life exposure is thought to be critical, which may affect treatment compliance and significantly increase costs. The majority of MS cases and controls in these studies are White and of European descent. There needs to be more research into whether vitamin D is also a risk factor for MS in other race/ethnic populations including Blacks and Hispanics. The evidence from observational studies and RCTs on the effects of vitamin D on MS disease activity and progression suggests that having high 25(OH)D levels reduces the development of new demyelinating lesions. Results on other outcomes have been mixed and well-designed RCTs of appropriate follow-up and power are needed to evaluate this, but significant challenges, including recruitment, costs, and appropriate vitamin D supplement dose to use, remain barriers.

## 9. Summary points

- There is strong evidence that vitamin D nutrition is a risk factor for MS as well as disease activity.
- 25(OH)D levels are inversely associated with both adult- and pediatric-onset MS.
- Sun exposure in childhood and adolescence is inversely associated with adult-onset MS.
- Among individuals with MS, evidence suggests that vitamin D beneficially affects relapse rates and new lesion development.

# Vitamin D and rheumatoid arthritis

Stephanie Harrison<sup>1</sup>, Elena Nikiphorou<sup>2,3</sup>, Louisa Jeffery<sup>4,5</sup>,  
Karim Raza<sup>4</sup> and Martin Hewison<sup>5</sup>

<sup>1</sup>Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom <sup>2</sup>Department of Rheumatology, King's College Hospital, London, United Kingdom <sup>3</sup>Centre for Rheumatic Diseases, King's College London, London, United Kingdom <sup>4</sup>Institute of Inflammation and Ageing Research, University of Birmingham, Birmingham, United Kingdom <sup>5</sup>Institute of Metabolism and Systems Research, University of Birmingham, Birmingham, United Kingdom

## OBJECTIVES

- Describe the immune interactions of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D that support a role for these metabolites as regulators of joint inflammation.
- Detail the association studies (including Mendelian randomization) that have linked low serum 25-hydroxyvitamin D with autoimmune rheumatoid disorders.
- Determine the efficacy of animal models in defining the impact of vitamin D on rheumatoid arthritis.
- Outline the randomized clinical trials that have explored the possible disease prevention and therapeutic benefits of vitamin D supplementation in rheumatoid arthritis.

[2]. RA pathophysiology appears to involve potential underlying genetic susceptibility [3,4] that is further exacerbated by environmental risk factors [5], resulting in the dysregulation of innate and adaptive immunity, and predisposition toward inflammatory autoimmunity rather than immune tolerance [6]. Like other autoimmune diseases documented in this book (see Chapter 97, Chapters 100–102, and Chapter 104), vitamin D deficiency (low serum 25-hydroxyvitamin D, 25(OH)D) has been proposed as a key environmental/dietary factor linked to the pathophysiology of RA [7]. In addition to the relationship between serum 25(OH)D concentrations and RA disease risk and severity, there is now also a well-documented mechanistic rationale for antiinflammatory effects of vitamin D that supports a beneficial function for vitamin D in RA patients. These two facets of vitamin D and RA are discussed in further detail in the following sections, along with the supplementation trials that have investigated the potential benefits of vitamin D supplementation in either preventing or managing RA disease.

## 1. Introduction

Rheumatoid arthritis (RA) is a chronic inflammatory/autoimmune form of arthritis characterized by synovitis of peripheral joints, with some extraarticular manifestations [1]. If left untreated, ongoing inflammation can result in the destruction of joint tissue, leading to a loss of joint function and potential disability. RA may also lead to premature mortality due, in part, to chronic inflammation promoting adverse cardiovascular health

## 2. Antiinflammatory effects of vitamin D

The interaction between vitamin D and innate and adaptive immunity is described in detail in Chapters 94–96. The central feature of these immunomodulatory responses of vitamin D is the ability of immune cells to metabolize 25(OH)D to active 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D) to support both intracrine and paracrine

immunomodulatory actions of  $1,25(\text{OH})_2\text{D}$ . As detailed earlier in Chapter 9, expression of the enzyme 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase (1 $\alpha$ -OHase) by antigen-presenting cells (APCs) such as macrophages and dendritic cells (DCs) is stimulated by damage- or pathogen-associated molecular patterns (DAMPs and PAMPs) acting via pattern recognition receptors (PRRs) such as the Toll-like receptor (TLR) system [8,9]. The net effect of this is to actively enhance localized concentrations of  $1,25(\text{OH})_2\text{D}$  within the immediate immune microenvironment. This, in turn, facilitates endogenous intracrine antibacterial (see Chapter 94) and antiviral (see Chapter 95) innate immune activity via vitamin D receptor (VDR)–mediated transcriptional responses [10]. However, localized synthesis of  $1,25(\text{OH})_2\text{D}$  is also central to inflammatory adaptive immune responses, as described in the following sections.

## 2.1 Antigen-presenting cells and extrarenal synthesis of $1,25(\text{OH})_2\text{D}$

One of the initial observations linking vitamin D and immune function was the expression of VDR by APCs such as macrophages [11,12] and DCs [13], and the ability of these cells to therefore respond to  $1,25(\text{OH})_2\text{D}$ . In particular,  $1,25(\text{OH})_2\text{D}$  and its synthetic analogs have been shown to suppress the maturation of DC, leading to attenuation of DC-induced T cell function [14]. This provided the first evidence of a tolerogenic role for  $1,25(\text{OH})_2\text{D}$  mediated via indirect effects on APC rather than direct effects on activated T cells, which unlike resting T cells are known to express VDR [15]. Subsequent studies using monocyte-derived DCs showed that the tolerogenic effects of  $1,25(\text{OH})_2\text{D}$  were associated with suppression of CD80, CD83, CD40, and class 2 major histocompatibility complex (MHC II) and increased apoptosis of mature DC [16,17]. CD4+ T cells activated in the presence of  $1,25(\text{OH})_2\text{D}$ -treated DC showed lower expression of the inflammatory cytokine interferon  $\gamma$  (IFN $\gamma$ ) underlining the indirect antiinflammatory effects of  $1,25(\text{OH})_2\text{D}$ .

Although both macrophages and DC express VDR and respond to  $1,25(\text{OH})_2\text{D}$ , the increased capacity of these cells for synthesis of  $1,25(\text{OH})_2\text{D}$  from  $25(\text{OH})\text{D}$  as they differentiate has highlighted a potential avenue by which  $25(\text{OH})\text{D}$  may also be able to influence immune function [18–20]. Studies using monocyte-derived DCs in coculture with T cells have shown that contact with T cells is sufficient to induce expression of the 1 $\alpha$ -OHase gene (*CYP27B1*) by DC [21]. The resulting DC 1 $\alpha$ -OHase activity enabled localized DC synthesis of  $1,25(\text{OH})_2\text{D}$  that was as effective as exogenous  $1,25(\text{OH})_2\text{D}$  in promoting antiinflammatory T cell responses in the cocultures. This intracrine action of

endogenously generated  $1,25(\text{OH})_2\text{D}$  by DC may be sufficient to modulate inflammatory T helper (Th) cell responses and also to generate tolerogenic regulatory T cells (Treg) within tissues such as the joints.

As shown in Fig. 103.1, a key intracrine action of vitamin D is to promote the generation of tolerogenic DCs (tolDCs) that are instrumental in directing tolerogenic T cell responses (IL-10 production and Treg generation). A similar intracrine mechanism may also support Treg generation via macrophages, as well as promoting regulatory B cells (Breg), which, like Treg, play a pivotal role in tolerogenic immune responses during inflammation [22]. The model in Fig. 103.1 shows how DC synthesis by DC is effective in promoting antiinflammatory/tolerogenic T cell responses in the setting of adequate access to  $25(\text{OH})\text{D}$  for metabolism to  $1,25(\text{OH})_2\text{D}$ , in other words under conditions of vitamin D sufficiency. Fig. 103.1 also illustrates the potential consequences of impaired APC synthesis of  $1,25(\text{OH})_2\text{D}$  in the setting of vitamin D deficiency, with mature DC (mDC) predominating instead of tolDC, and mDC and macrophages promoting an inflammatory cytokine milieu and inflammatory Th1/Th17 T cells rather than Treg and Breg.

The overarching message from this hypothetical model system is that healthy (sufficient) serum levels of  $25(\text{OH})\text{D}$  may play a crucial role in suppressing inflammatory immune responses associated with autoimmune diseases such as RA. In this model, the pivotal effects of  $25(\text{OH})\text{D}$  are assumed to be mediated through its metabolism to  $1,25(\text{OH})_2\text{D}$  by APC and subsequent intracrine effects on these cells that indirectly influence T and B cell function. However, it is important to recognize that the synthesis of  $1,25(\text{OH})_2\text{D}$  by APC may also have paracrine effects within the immune microenvironment [8]. In particular, the differential expression of VDR and 1 $\alpha$ -OHase by DC as they differentiate suggests that more active synthesis of  $1,25(\text{OH})_2\text{D}$  by mDC expressing lower levels of VDR may facilitate paracrine effects of  $1,25(\text{OH})_2\text{D}$  on immature DCs (iDCs), which are known to have lower levels of 1 $\alpha$ -OHase but higher levels of VDR [23].

## 2.2 Helper, cytotoxic, and regulatory T cells

The actions of vitamin D in regulating adaptive immune responses via effects on Th and Treg T cell subsets are described in greater detail in Chapter 96.

$1,25(\text{OH})_2\text{D}$  plays an important role in regulating T cell phenotype [24–27]. In particular,  $1,25(\text{OH})_2\text{D}$  has been shown to suppress inflammatory interleukin-17 expressing Th17 cells [28] and Th1 cells [29], while promoting Th2 cells [30] and Treg [31,32].  $1,25(\text{OH})_2\text{D}$  can also promote immune activity by enhancing effector

**FIGURE 103.1 Vitamin D status and synovial immune cell function.** In RA, vitamin D deficiency favors inflammatory responses and osteoclast-mediated bone loss. Autoantigens such as citrullinated matrix proteins are presented to  $CD4^+$  T cells by professional APCs such as DCs or monocytes and macrophages. DCs, monocytes, macrophages, and B cells express the vitamin D-activating enzyme  $1\alpha$ -hydroxylase ( $1\alpha$ -OHase) and can generate  $1,25(OH)_2D$  from  $25(OH)D$  under conditions of vitamin D sufficiency. Although expression of  $1\alpha$ -OHase is enhanced in mDCs, these cells promote a  $T_H1$  cell or  $T_H17$  cell phenotype in the absence of sufficient  $25(OH)D$ .  $IFN\gamma^+$   $T_H1$  cells promote APC maturation, whereas  $T_H17$  cells act on FLSs to promote release of inflammatory cytokines and MMPs and to express RANKL. RANKL expression by FLSs,  $T_H17$  cells, and  $FCRL4^+$  B cells drives osteoclastogenesis and bone erosion. Vitamin D deficiency also favors the production of IL-21 and generation of  $T_{FH}$ -mediated germinal centers for B cell activation and differentiation. By contrast, in conditions of vitamin D sufficiency,  $25(OH)D$  is metabolized to  $1,25(OH)_2D$  by  $1\alpha$ -OHase-expressing APCs, promoting the differentiation of tolDCs, which favor the differentiation of  $T_{REG}$  cells and  $B_{REG}$  cells.  $1,25(OH)_2D$  produced by APCs or  $B_{REG}$  cells might also act directly on T cells and B cells to promote an antiinflammatory phenotype, and enhances expression of OPG over RANKL by FLSs, thereby reducing osteoclastogenesis. Cell differentiation pathways (black arrows), cytokine production and function (red arrows), and vitamin D metabolism (blue arrows).  $1,25(OH)_2D$ , 1,25-dihydroxyvitamin D;  $25(OH)D$ , 25-hydroxyvitamin D; ACPA, anticitrullinated protein antibody; APC, antigen-presenting cell;  $B_{REG}$ , B regulatory cell; DC, dendritic cell;  $FCRL4$ , Fc receptor-like protein 4; FLS, fibroblast-like synoviocyte; iDC, immature dendritic cell; mDC, myeloid dendritic cell; MMP, matrix metalloproteinase; OPG, osteoprotegerin; RA, rheumatoid arthritis; RANK, tumor necrosis factor receptor superfamily member 11A; RANKL, tumor necrosis factor ligand superfamily member 11;  $T_{FH}$ , T follicular helper cell;  $T_H$ , T helper cell; tolDC, tolerogenic dendritic cell;  $T_{REG}$ , T regulatory cell. T cell responses including cytotoxic function [25], via potential effects to promote T cell receptor expression and T cell activation [33], and by modulating natural killer (NK) cells [34]. Effects of  $1,25(OH)_2D$  have also been described for natural killer T (NKT) cells, and NKT cell development is impaired in mice lacking the VDR gene [35].

Studies using activated peripheral blood mononuclear cells (PBMC)-derived  $Th17$  cells from treatment-naïve patients with early RA have shown that treatment with  $1,25(OH)_2D$  reduces expression of IL-17 and  $IFN\gamma$  in a similar fashion to effects of another antiinflammatory steroid, dexamethasone [36]. By contrast in this study,  $1,25(OH)_2D$  stimulated expression of IL-4,

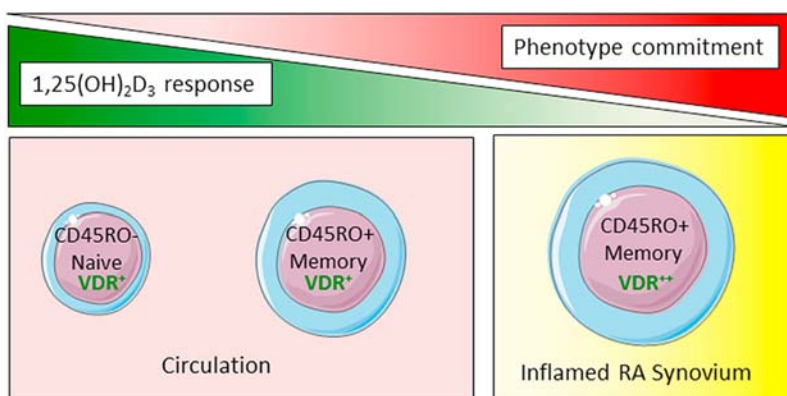

whereas IL-4 was suppressed by dexamethasone. As a consequence, the IL-4:IL-17 ratio, which is elevated in early RA patients, was decreased with  $1,25(\text{OH})_2\text{D}$  but increased with dexamethasone [36]. The conclusion from these studies was that  $1,25(\text{OH})_2\text{D}$  as a treatment for RA may be more effective and have less detrimental side effects than more traditional antiinflammatory therapeutics such as glucocorticoids. Other groups have reported similar effects of  $1,25(\text{OH})_2\text{D}$  in suppressing inflammatory IL-1, IL-6, IL-17, IL-22, and TNF $\alpha$  in T cells from RA patients while simultaneously promoting IL-4 [37]. Recent studies of RA patients receiving the IL-6 receptor antibody tocilizumab showed better response to this treatment when patients were vitamin D sufficient [38]. Analysis in vitro of PBMC-derived T cells from these patients showed that tocilizumab and  $1,25(\text{OH})_2\text{D}$  had a synergistic effect in suppressing Th17 cells [38].

Chronic synovial inflammation is a hallmark of RA and involves the accumulation of inflammatory T cells within the synovium. However, although  $1,25(\text{OH})_2\text{D}$  has been shown to exert potent effects in suppressing Th1 and Th17 cells using PBMC from RA patients, relatively few studies have used T cells from actual RA patient synovial fluid. Work by our group compared T cell responses to  $1,25(\text{OH})_2\text{D}$  using cells isolated from paired blood and synovial fluid samples [39]. One notable difference between the T cell populations from blood and synovial fluid is that synovial T cells are predominantly memory T cells, which constitute only approximately 50% of circulating T cells [40]. Analysis of T cells from RA patients showed that both naïve (immunologically unchallenged) T cells and memory T cells are able to respond to  $1,25(\text{OH})_2\text{D}$ , but inhibition of inflammatory cytokines was more pronounced for naïve T cells when compared with memory T cells [39]. This lack of responsiveness to  $1,25(\text{OH})_2\text{D}$  was even more pronounced in memory T cells from RA synovial fluid compared with memory T cells from paired blood

samples in the same RA patient. T cell responses to  $1,25(\text{OH})_2\text{D}$  appear to be dependent on the commitment of T cells to a particular phenotype. Conversion of cytokine naïve T cells into inflammatory effector cells is strongly suppressed by  $1,25(\text{OH})_2\text{D}$ . Conversely,  $1,25(\text{OH})_2\text{D}$  is much less effective in suppressing an existing T cell phenotype, despite similar expression of VDR in these cells (Fig. 103.2). T cells from synovial fluid exhibit a more committed phenotype relative to circulating T cells. Consequently,  $1,25(\text{OH})_2\text{D}$  is much less effective in suppressing inflammatory T cells from synovial fluid than from circulating blood, even in cells from the same RA patient. The overall conclusion from these observations is that  $1,25(\text{OH})_2\text{D}$  may be less effective as a treatment for diseases such as RA once the disease has become established. Thus, either higher doses of  $1,25(\text{OH})_2\text{D}$  are needed to counter diseases such as RA or attention should be refocused on the use of vitamin D in disease prevention.

In addition to the accumulation of inflammatory T cells within the synovium, RA is also characterized by the presence of senescent T cells, which are sensitive to activation by self-antigens within the joint [42] and continue to produce proinflammatory cytokines. Serum vitamin D status has been linked to telomere length in leukocytes, and this, in turn, may help reduce the rate of T cell senescence [43]. In support of this proposal, vitamin D supplementation in vivo has been reported to increase telomerase activity in PBMCs [44]. The importance of telomerase and T cell senescence in RA is underlined by the fact that even naïve  $\text{CD4}^+$  T cells from patients with RA have impaired telomerase activity [45], which is independent of RA disease activity and duration [42]. Telomerase deficiency could therefore be a potential preclinical marker for RA [42], and increasing serum  $25(\text{OH})\text{D}$  levels through vitamin D supplementation may help to increase telomerase activity, and thus reduce the risk of developing RA, while potentially also slowing the progression of RA.

**FIGURE 103.2** Memory T cells from synovial fluid are less sensitive to  $1,25(\text{OH})_2\text{D}$  than circulating naïve or memory T cells. Both naïve ( $\text{CD45RO}^-$ ) and memory ( $\text{CD45RO}^+$ ) T cells are able to respond to  $1,25$ -dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}_3$ ), but inhibition of inflammatory cytokines is more pronounced for naïve T cells and becomes less effective upon transition from naïve to memory. Furthermore, although naïve to memory transition accounts for most of the loss in  $1,25(\text{OH})_2\text{D}_3$  responsiveness, memory T cells from synovial fluid (SF) show a further decline in  $1,25(\text{OH})_2\text{D}_3$  sensitivity when compared with circulating memory cells. ## 2.3 B cells

Although most studies of adaptive immune function in autoimmunity have to date focused on inflammatory and regulatory T cell function, there is growing interest in the role that B cells play in diseases such as RA [46]. B cells are able to exert positive effects on inflammation through the production of cytokines and associated effects on the differentiation of inflammatory Th17 cells [47]. B cells are also associated with autoantibody production following plasma cell differentiation [48] and contribute to macrophage differentiation [49]. In common with autoreactive T cells, pathogenic B cells are also a feature of RA [50]. As with T cells, the inflamed synovium in RA is characterized by accumulation of B cells [51], and therapies targeted at B cell depletion have recently been expanded from use with B cell lymphomas to the treatment of autoimmune diseases [52]. However, it is important to recognize that, in diseases such as RA, the benefits of pathogenic B cell depletion are offset by potential detrimental effects of Breg depletion. As shown in Fig. 103.1, Bregs play a key role in maintaining tolerogenic immune responses during inflammation [21], and thus, B cell targeted therapies for RA (and other autoimmune diseases) require a delicate balance between the two opposing features of B cells during inflammation.

In contrast to the detailed characterization of T cell responses to 1,25(OH)<sub>2</sub>D, relatively little is known about effects of 1,25(OH)<sub>2</sub>D on B cells in general but particularly in the setting of RA. B cell responses to 1,25(OH)<sub>2</sub>D may include indirect effects via T cell modulation [53], or direct B cell effects on class switching [54], IL-10 production [55] and CCR10 production [56]. Although specific effects of vitamin D on Breg function have yet to be described, the established effects of 1,25(OH)<sub>2</sub>D on B cell IL-10 production [55], and the inverse relationship between IL-10-producing B cells and RA disease activity [57] suggests that 1,25(OH)<sub>2</sub>D may act to support Breg function during inflammation. In a murine pregnancy and asthma model, serum vitamin D deficiency was associated with decreased levels of both Treg and Breg in conjunction with increased levels of inflammatory cytokines such as IL-17 [58]. It therefore seems likely that in autoimmune diseases such as RA, vitamin D will act to promote not only Tregs, but also Bregs. As shown in Fig. 103.1, vitamin D deficiency may therefore also act to impair Breg function and thus predispose to autoimmunity.

## 2.4 Fibroblasts

In addition to innate and adaptive immune cells involved in inflammatory activity, the synovial tissue of joints affected by RA is also characterized by the

presence of fibroblast-like synoviocytes (FLSs) [59]. Initially, FLSs were considered as simply the platform for immune cell interactions [60]. However, it is now clear that FLSs play an active role in the pathogenesis of RA [61,62], and also mediate joint destruction by secretion of cartilage-degrading matrix metalloproteinases, cathepsins, and RANKL (which promotes osteoclastogenesis) and Dickkopf-related protein 1, which inhibits osteoblast function) [61]. Cultured FLSs treated with 1,25(OH)<sub>2</sub>D show decreased levels of inflammatory cytokines and MMPs [63], suggesting that active vitamin can attenuate FLS function. More recent studies have shown that 1,25(OH)<sub>2</sub>D inhibits the viability and promotes the apoptosis of FLS from RA patients [64]. This action is mediated in part by cooperation with DBP, with lower levels of this protein in the synovial tissue and synovial fluid of RA patients [64]. The overall conclusion from these studies was that DBP enhances the effects of 1,25(OH)<sub>2</sub>D on FLS viability and apoptosis. In contrast to these FLS suppressive effects, 1,25(OH)<sub>2</sub>D has been shown to increase RANKL expression in FLS [65]. Although this suggests that 1,25(OH)<sub>2</sub>D promotes osteoclastogenesis and the potential bone loss associated with this, 1,25(OH)<sub>2</sub>D also stimulated FLS production of the RANKL decoy receptor osteoprotegerin (OPG) to significantly increase the OPG/RANKL ratio [65]. In this way, FLS responses to 1,25(OH)<sub>2</sub>D within the synovium may act to decrease the abundance of osteoclasts and thus help to reduce the pathological bone loss associated with RA (see Fig. 103.1). In common with APC within the immune system, FLSs from the synovium of RA patients expressing 1 $\alpha$ -OHase are able to synthesize 1,25(OH)<sub>2</sub>D from 25(OH)D [66,67], thus providing a mechanism by which vitamin D status (serum 25(OH)D levels) can influence FLS function.

## 3. Vitamin D and mouse models of RA

The association between vitamin D and autoimmune disease such as RA has been explored using animal models. This includes analysis of mice under conditions of 25(OH)D deficiency, and/or following supplementation with vitamin D or active 1,25(OH)<sub>2</sub>D. Likewise, mice with knockout of the *Vdr* and *Cyp27b1* genes have provided important insights into the potential causative impact of vitamin D deficiency on RA disease.

Initial studies using two models of murine RA disease, Lyme arthritis and collagen-induced arthritis, induced by infection with *Borrelia burgdorferi* or injection with type II collagen, respectively, showed that supplementation with 1,25(OH)<sub>2</sub>D (20 ng/day) reduced the symptoms of disease associated with both of these murine models of RA [68]. This included scoring of ankle and paw inflammation in living animals and tissue

analysis of joints following euthanasia. Subsequent studies suggested that the effect of supplementary 1,25(OH)<sub>2</sub>D in protecting against murine forms of RA (as well as murine multiple sclerosis) is due, in part, to the induction of interleukin-4 (IL-4) [69]. However, in a more recent study of 1,25(OH)<sub>2</sub>D-mediated protection against collagen-induced arthritis, amelioration of RA disease severity in mice was associated with downregulation of interferon- $\gamma$  (IFN $\gamma$ ) and interleukin-17 (IL-17)-expressing T cells [70]. Conversely, treatment with 1,25(OH)<sub>2</sub>D enhanced expression of Treg cells, indicating that the protective effect of vitamin D on murine RA involves both antiinflammatory and tolerogenic effects. These effects of 1,25(OH)<sub>2</sub>D were also shown to be mediated, in part, by induction of microRNA 124 [70].

In common with other autoimmune diseases, initial murine studies of RA and vitamin D have focused primarily on the impact of supplemental oral 1,25(OH)<sub>2</sub>D on effector T cell or Treg expression and function as a conduit for ameliorating tissue inflammation. However, an alternative strategy is to target tolerance via actions on APCs such as DCs. One such study utilized subcutaneous administration of liposomes encapsulating ovalbumin and 1,25(OH)<sub>2</sub>D to reduce MHC class II expression in DC from draining lymph nodes and thus promote Treg expression and function [71]. The net effect of this was to reduce RA disease severity in the mice by suppression of antigen-specific memory T cell differentiation and function.

In contrast to human studies, vitamin D supplementation in mouse models of autoimmune disease has primarily involved treatment with 1,25(OH)<sub>2</sub>D rather than conventional vitamin D supplementation used for human studies. In most cases, this strategy ameliorated the specific disease, suggesting that simply raising circulating 1,25(OH)<sub>2</sub>D is sufficient to modulate inflammatory disease in a specific animal model. This contradicts the fundamental localized metabolism of 25(OH)D to 1,25(OH)<sub>2</sub>D defined in human studies of inflammation [8] and suggests that the intracrine 25(OH)D model of metabolism may not be generalizable to animal models *in vivo*. It should also be recognized that hypercalcemic effects of 1,25(OH)<sub>2</sub>D may be less evident in animal models of inflammation because of the relatively short-term treatments used in this setting relative to scenarios of human clinical therapy. Thus, extrapolation of animal models of vitamin D and inflammatory disease must be viewed with some caution.

In common with studies of dietary vitamin D deficiency, murine knockout of vitamin D genes such *Vdr* and *Cyp27b1* has been shown to exacerbate mouse versions of autoimmune disease. It therefore seems likely that the vitamin D system plays some role in mediating normal immune responses that protect against inflammatory disease. The first study that illustrated this involved

crossing *Vdr* knockout mice with the human tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) transgenic mouse (hTNFtg) [72]. The resulting cross-bred offspring showed increased clinical symptoms of inflammatory arthritis and increased numbers of macrophage in inflamed joints, suggesting that expression of VDR is central to normal macrophage antiinflammatory function in hTNFtg mice [72]. In addition, macrophages from the *Vdr* knockout/hTNFtg mice showed increased potential to differentiate into bone-resorbing osteoclasts, suggesting that VDR expression may also be important in limiting the cartilage destruction and bone erosion associated with synovial inflammation. Exacerbation of experimental inflammatory arthritis has also been observed in mice lacking the 1 $\alpha$ -hydroxylase enzyme. Knockout mice for *Cyp27b1* subjected to collagen-induced arthritis showed increased clinical evidence of joint inflammation, as well as elevated rheumatoid factor and C-reactive peptide [73]. Intraperitoneal administration of 1,25(OH)<sub>2</sub>D (1  $\mu$ g/kg every other day) rescued the effects of *Cyp27b1* knockout by restoring serum 1,25(OH)<sub>2</sub>D levels to wild-type levels [73]. In addition to showing that loss of circulating 1,25(OH)<sub>2</sub>D in *Cyp27b1* knockout mice was associated with increased levels of inflammatory cytokines, the authors also noted hyperplasia of FLSs and showed that this was countered by peritoneal administration of 1,25(OH)<sub>2</sub>D, which decreased FLS proliferation while also stimulating apoptosis of these cells [73]. As with studies of 1,25(OH)<sub>2</sub>D administration in other mouse models of RA, the overarching conclusion from the observations of *Cyp27b1* knockout mice is that enhanced circulating levels of 1,25(OH)<sub>2</sub>D alone may be sufficient to ameliorate key features of inflammatory arthritis, at least in mouse models of this disease.

#### 4. Vitamin D deficiency and RA disease risk, severity, and progression

In common with many other human health conditions detailed in this section of the book, a crucial observation linking vitamin D and RA has been the association between low serum 25(OH)D status and either the incidence or disease severity of RA. Systematic reviews have reported a relationship between serum 25(OH)D and clinical and laboratory indices of RA disease activity [74,75]. Although these metaanalyses identified important differences between the studies included in the systematic reviews, both studies reported lower levels of serum 25(OH)D in RA patients versus healthy controls, and both also reported an inverse relationship between serum 25(OH)D and RA disease activity. A selection of the most prominent reported studies of serum 25(OH)D levels in patients with RA is shown in Table 103.1.

**TABLE 103.1** Association between serum vitamin D levels and RA disease activity.

Study References	Population size and location	Disease duration	Analytical method	Metabolite measured	25(OH)D deficiency	25(OH)D lower in HC versus RA	Association of vitamin D with disease parameter(s)
[76]	RA = 96, Germany	Mean 12.2years (range 6 m–to 38years)	RAI	1,25(OH) <sub>2</sub> D	Unclear	n/a	Neg: disease activity Pos: urinary collagen cross-links ↑ DA is assoc. neg. Ca balance and ↓ bone formation
[77]	RA = 118, HC = 75, Estonia and Italy	Not stated	RAI	25(OH)D	n/a	n/a	Neg: DAS-28; however, correlation varied according to time of year and country of origin
[78]	RA = 266 (African American)	Mean 31.2m (SD = 7.3m)	Unclear	25(OH)D	<15 ng/mL	n/a	Null

There is considerable heterogeneity with the studies presented in this table, with regard to geographical location, methodology for measuring circulating 25(OH)D, and the precise definition of vitamin D deficiency in each report. Moreover, the majority of listed studies are observational or cross-sectional in nature, and thus a causal role for vitamin D in RA cannot necessarily be inferred. Nevertheless, the prevalence of vitamin D deficiency in RA patients and negative correlation between serum 25(OH)D and various markers of RA disease strongly suggest that vitamin D has some impact on RA disease. This is illustrated by recent systematic reviews of the association between vitamin D and RA. A metaanalysis of 15 studies of vitamin D status and RA using 1143 patients and 963 controls showed that serum 25(OH)D deficiency was more common in RA patients (55.2%) relative to healthy controls (33.2%) [74]. Further analysis of 13 of these studies (including 924 RA patients) showed a significant inverse correlation between serum 25(OH)D concentration and RA disease activity as defined by RA disease activity score 28 joints (DAS28) [74]. Another metaanalysis published at the same time as the study described before reported similar data using 24 published reports and 3489 RA patients also showed lower levels of serum 25(OH)D in RA patients and correlation between 25(OH)D and DAS28 [75]. The conclusion from both of these studies is that serum 25(OH)D concentration is associated with both the risk of developing RA and subsequent disease severity.

Increased RA onset, severity, and progression has been reported for winter months, consistent with the decline in serum 25(OH)D levels that is observed following peak UVB-induced levels of 25(OH)D in later summer [128]. In common with many other diseases that have been linked to vitamin D deficiency, low serum 25(OH)D is not necessarily a causative factor in RA. It is possible that severe RA may impair serum 25(OH)D levels by limiting patient access to UV-mediated synthesis of vitamin D. Inflammatory autoimmune disease may also act to suppress serum 25(OH)D levels either at the level of renal clearance of 25(OH)D via decreased availability of vitamin D-binding protein (DBP), or through an as-yet-unidentified effect on metabolism of vitamin D to 25D. It is also important to recognize that vitamin D deficiency may impact RA beyond the central pathophysiological effects on inflammatory joint damage. Low serum levels of 25(OH)D may contribute to established comorbidities of RA such as the bone disease osteoporosis [129]. Vitamin D deficiency is one of the key risk factors for osteoporosis and potential bone fractures in RA patients [89,97,105,127,130], and this is further exacerbated by the widespread therapeutic use of glucocorticoids in RA patients; a major contributor to bone loss in its own right [131]. Thus, the use of

antiinflammatory steroids against the backdrop of vitamin D deficiency may be a worst-case scenario for potential bone loss in RA patients.

Another comorbidity of RA that is likely to be affected by vitamin D status is the pain associated with the inflammatory disease. Pain features strongly in the RA disease parameters described in Table 103.1, but may persist even when the disease is in remission. Several studies have specifically explored the impact of vitamin D on this facet of RA disease. A multicenter cross-sectional study of 93 patients visiting outpatient rheumatology clinics showed that neuropathic pain was 5.8 times more prevalent among patients with serum 25(OH)D levels less than 20 ng/mL compared with those with 25(OH)D levels that were higher than 30 ng/mL [132]. The overarching conclusion from this study was that serum 25(OH)D concentrations were a good predictor of likely neuropathic pain in RA patients. Other studies have reported that supplementation with the active form of vitamin D, 1,25(OH)<sub>2</sub>D (60,000 IU once weekly in combination with 1000 mg/day calcium carbonate), improves pain relief [133]. In 150 treatment-naïve early RA (<2 years) subjects attending rheumatology clinic, visual analog scale (VAS) and disease activity score-28 days (DAS-28) were significantly improved in the 1,25(OH)<sub>2</sub>D-treated subjects compared with the calcium-only group [133]. A link between vitamin D and RA disease pain has also been described for fibromyalgia, a chronic disorder associated with severe pain that is one of the most common rheumatological conditions in patients presenting at rheumatology clinics [134]. Supplementation with vitamin D (bolus dose of 100,000 IU followed by 4000 IU/day for 16 weeks) showed improved chronic back pain vitamin D-deficient (<30 ng/mL serum 25(OH)D at baseline) or overweight adults who were otherwise healthy [135]. Similar results were also observed for a cohort of 68 patients with chronic lower back pain who were treated with 60,000 IU/week vitamin D for 8 weeks [136]. In a similar fashion to that observed for other human health conditions, the effect of vitamin D supplementation in managing pain appears to be most pronounced in patients with low serum 25(OH)D at baseline, providing another potential advantage in assessing vitamin D status in RA patients.

One approach to resolve the issue of whether vitamin D deficiency is a causative factor in RA is through the use of vitamin D supplementation randomized control trials to determine if elevation of serum 25(OH)D levels can prevent the onset or progression of RA disease. This strategy is discussed in greater detail in Section 5 and Table 103.2 of this chapter. Further insight into the possible benefits of vitamin D in preventing RA has also been provided by food fortification programs (see Chapter 58). Reported studies of a large cohort of

TABLE 103.2 Vitamin D supplementation trials in rheumatoid arthritis.

Study	Study participants (eligible number of RA patients + DMARD tx)	Treatment groups/trial design/BL 25(OH)D	Primary and secondary outcome measures	Summary of key findings
[137]	RA = 19 (on MTX ± GC, active dx)	2 microg/day oral alphacalcidol for 3/12 in 2 groups; mod + highly active RA. Control group = same patients data collected over 3 months prior to suppl. Open-label trial	ESR, CRP, EMS, Richie index, Lee index at 3 months	CRP, SJC, TJC, Richie index, and Lee index all significantly decreased after 3/12. RF and CRP were decreased, but this was not statistically significant.
[138]	RA = 121 (on triple DMARDs)	500 IU 1,25(OH) <sub>2</sub> D <sub>3</sub> + CaCO <sub>3</sub> versus CaCO <sub>3</sub> Open-label 25(OH)D < 20 ng/mL at BL	Pain relief assessed by patient VAS at first relief of pain and again at 3/12	No difference in time in achieving first pain relief; however, there was higher pain relief in the 1,25(OH) <sub>2</sub> D <sub>3</sub> group at 3/12 (NNT = 5).
[139]	RA = 117 (on MTX ± HCQ/CQ, active dx)	50,000 IU/week vitamin D <sub>3</sub> for 3 months versus placebo Double-blinded trial	>0.6 or >1.2 improvement in DAS28 at week 12	No improvement in outcome measures reported.
[140]	RA = 80 (remission for 2/12)	Vitamin D <sub>3</sub> 50,000IU/week versus placebo Double-blinded RCT 25(OH)D levels were <30 ng/mL at BL	DAS28 as a marker of relapse, over 6/12	No statistically significant reduction in relapse rate was observed.
[141]	RA = 22 (on DMARDs)	25(OH)D < 25 ng/mL at BL placebo or vitamin D2 50,000 IU ×3 times/week for 4 weeks, then 50,000 IU ×2/month for 11 months	Primary = serum PTH Secondary = BMD, DAS28, HAQ, and SF36 scores and cytokines	No improvement in PTH, BMD, RA disease activity or cytokines
[142]	RA = 377 (RA in remission)	Alfacalcidol 0.25 microg BD for 24 months in 25(OH)D def. RA versus placebo versus RA with normal 25(OH)D levels and no treatment Open-label Deficiency = 25(OH)D < 30 ng/mL	VAS, SHC, TJC, CRP, ESR, and DAS28 every 2–3/12	Normal vitamin D assoc. with ↓ recurrence. No difference was observed with or without vitamin D suppl. In RA with low vitamin D.
[143]	Early RA = 39 (Tx naïve), HC = 31	MTX + GC versus MTX + GC + 300,000 IU vitamin D (one-off dose) Double-blind RCT	T Cell phenotypes, OC precursors, inflammatory cytokines, clinical parameters at 3/12	Reduced IL-23, increased GlobalHealth Score in vitamin D group
[144]	RA = 73 (on DMARDs, active dx)	60,000 IU/vitamin D <sub>3</sub> /week for 6 weeks then 60,000 IU/month for	Improvement in DAS28-CRP, vitamin D status	↓ DAS28-CRP and ↑ vitamin D > 20 ng/mL in the tx group

Study	Study participants (eligible number of RA patients + DMARD tx)	Treatment groups/trial design/BL 25(OH)D	Primary and secondary outcome measures	Summary of key findings
[145]	RA = 59 (active disease, DAS28 > 2.6, 17 yrs disease)	3/12 Open-label 25(OH)D < 20 ng/mL at BL + DAS28-CRP > 2.6  Double-blinded RCT, 100,000 IU vitamin D <sub>3</sub> or placebo 25(OH)D < 30 ng/mL at BL	Primary = HAQ; secondary = improvement in DAS28ESR, DAS28CRP, ESR, CRP, RAID score, fatigue (EVA and FACIT), and SF36	HAQ scores improved in vitamin D arm Only ESR and CRP improved in secondary markers
[146]	RA = 108 (active disease mean 82 months, on DMARDs)	Serum 25(OH)D mean 22 ng/mL (43% < 20 ng/mL) Vitamin D3 100,000 IU/month	DAS28CRP, VAS, serum 25(OH)D	VAS higher in 25(OH)D deficiency Supplementation ↓ VAS only in 25(OH)D deficiency
[133]	RA = 150 (treatment-naïve early RA < 2 years)	60,000 IU 1,25(OH) <sub>2</sub> D <sub>3</sub> /week + CaCO <sub>3</sub> carbonate (1000 mg/day), placebo = CaCO <sub>3</sub>	Primary = time for pain relief and VAS Secondary = change in DAS28	↓ VAS and DAS28 scores but no effect on time to pain relief
[147]	RA = 2534 (all received DMARDs —MTX, HCQ, LEF)	4.4 ± 4.9 months. Varied. 1,25(OH) <sub>2</sub> D <sub>3</sub> (0.25–0.5 µg/day), or CaCO <sub>3</sub> and vitamin D (200–400 IU/day)	Primary = % patients with moderate/good response to RA treatment at 3, 6, 12, and >12 month Secondary = disease activity (VAS, SHC, TJC, CRP, ESR, and DAS28)	No difference in primary or secondary outcomes
[148]	25,871 healthy subjects, >50 years old, no RA	Vitamin D <sub>3</sub> (2000 IU/day) or placebo, and omega 3 fatty acids (1000 mg/day) or placebo, or both. For median 5.3 years	Primary = all incident self-reported autoimmune disease. Followed by medical confirmation Secondary = individual autoimmune diseases	Vitamin D with or without omega 3 fatty acids reduced autoimmune disease by 22% 40% decrease in RA with vitamin D (only 40 reported cases)

BD, twice daily; BL, baseline; CaCO<sub>3</sub>, calcium carbonate; CQ, chloroquine; CRP, C-reactive protein; DAS, disease activity score; DAS28, DAS 28 joints; DMARDs, disease-modifying antirheumatic drugs; EMS, early morning stiffness; ESR, erythrocyte sedimentation rate; GCs, glucocorticoids; GHS, Global Health Score; HAQ, Health Assessment Questionnaire Disability Index; HCQ, hydroxychloroquine; LEF, leflunomide; MTX, methotrexate; NNT, number needed to treat; RA, rheumatoid arthritis; RAID score, rheumatoid arthritis impact of disease; RF, rheumatoid factor; SF36, 36-Item Short Form Health Survey; SJC, swollen joint count; TJC, tender joint count; Tx, treatment; VAS, visual analogue scale.

patients with rheumatic diseases from Finland, where fortification of foods with vitamin D has been routine for 20 years, showed that vitamin D deficiency was relatively low in RA patients from this particular country [149]. Thus, it is important to recognize that there may be significant geographical variations when assessing associations between vitamin D and RA, and when planning supplementation trials, particularly in countries where fortification of food is common. However, some insight into the potential causative effects of vitamin D status on RA can also be derived from studies of the genetics of vitamin D metabolism and function, and this is discussed in greater detail in [Section 4](#).

## 5. Genetic variation in the vitamin D system and RA

Genetic analysis of links between the vitamin D system and RA initially focused on single nucleotide polymorphisms (SNPs) in the *VDR* gene and included analysis of RA disease risk and severity. However, in view of the well-established link between vitamin D and bone disease, *VDR* gene variants have also been studied with respect to bone loss in RA patients. Early studies of the *VDR* gene using 120 Spanish patients with RA showed weak association of *Bsm1* and *Taq1* SNPs with early-onset RA in female patients [150]. In a similar study from France using families with RA and healthy controls, *Fok1* polymorphisms were associated with RA [151]. Since these initial publications, there have been many subsequent studies of *VDR* SNPs and RA, using geographically distinct cohorts. A recent systematic review of these publications utilized 23 eligible studies to conclude *Fok1* was protective against RA in general but particularly in Asians and Europeans [152]. In African and Arabic cohorts, *Taq1* decreased RA but showed no effect in the overall analysis. Contrary to earlier studies, *Bsm1* did not appear to associate with RA in this metaanalysis. The overarching conclusions from this collection of studies was that genetic variations with the *VDR* were linked to RA disease risk, although there was significant geographical variation in which SNPs were informative. Furthermore, in common with many other studies of *VDR* gene variations and human disease, it is still unclear what specific 1,25(OH)<sub>2</sub>D signaling mechanism is affected by the SNPs associated with RA.

In addition to assessing the impact of *VDR* polymorphisms on risk of RA, several studies have also investigated possible effects on RA disease severity and associated complications. In a study of 123 patients from Spain with RA, the *bb* genotype of *Bsm1* was associated with less severe disease [153]. In the context of the *VDR*, the most commonly studied complication of RA is

bone loss. *Taq1* SNPs have also been shown to be associated with bone loss in women [154,155]. Similar observations have also been made in a cohort of male and female RA patients from Hungary [156]. However, a study in a Korean cohort showed no relationship between *VDR* SNPs and RA-associated bone erosion [157]. Similarly, a study in a German cohort of 62 RA patients and 40 healthy controls showed no association between *VDR* SNPs and markers of bone turnover [158].

Although the *VDR* gene has been the most widely studied with respect to effects on RA risk and disease severity and complications, genetic variations in other components of the vitamin D system have also been assessed in patients with RA. Prominent among these are variations in the gene for DBP (GC). In one study, proteomic and mass spectrometry analysis of synovial tissue from 10 patients with RA highlighted possible involvement of DBP in RA, with lower levels of DBP detected in tissue from these patients [159]. Subsequent GC genotyping in a larger group of RA patients and healthy controls showed that GC SNPs were associated with RA disease risk [159]. In another study of 1957 RA patients from Japan, a GC SNP was shown to be associated with lower serum levels of 25(OH)D and also increased hip fracture risk in the RA patients [160]. Genetic variations in genes for two vitamin D metabolism enzymes, 25-hydroxylase (*CYP2R1*) and *CYP27B1*, have been shown to be associated with increased risk of RA [161]. Although SNPs in *VDR* and *CYP24A1* were not associated with RA in this study, methylation levels of *CYP27B1* and *VDR* were both linked to RA disease risk [161].

The overarching message from studies of individual SNPs is that genetic variations in genes from the vitamin D system may influence both the serum levels of 25(OH)D in RA patients and risk of RA disease itself. As detailed in Chapter 60, various SNPs in the vitamin D system contribute to the genetic component of circulating 25(OH)D levels. This, in turn, has enabled prediction of the genetic component of serum 25(OH)D, based on combinations of SNPs associated with the handling and metabolism of vitamin D, which can be used in Mendelian randomization (MR) analyses to assess the possible impact of serum 25(OH)D on disease risk. The advantage of this approach is that it predicts a possible lifetime exposure to higher or lower serum 25(OH)D, and thus, any positive association with a disease is more likely to be causative rather than a consequence of the disease (see Chapter 61 for specific details of MR analysis). Initial MR analysis of almost 2000 RA patients did not support an effect of low predicted serum 25(OH)D on RA disease risk [162]. A subsequent study of patients with RA or systemic lupus erythematosus reported similar conclusions [163]. However, most vitamin D MR analyses to date have assumed a linear

relationship between genetically determined serum 25(OH)D and disease risk or severity. The recent observation of a nonlinear association between genetically determined 25(OH)D for overall mortality [164] and cardiovascular disease [165] in a large cohort of UK Biobank samples is consistent with a threshold effect where disease risk was significantly higher for those individuals with serum 25(OH)D less than 50 nmol/L. It will be interesting in future studies to see if there is a similar nonlinear threshold effect for genetically predicted serum 25(OH)D and RA.

## 6. Effects of supplementary vitamin D on RA

In common with other extraskeletal diseases where association studies have linked to vitamin D deficiency, there have been far fewer studies that have investigated possible beneficial effects of vitamin D supplementation on RA disease. This is due in part to the inherent difficulties in executing vitamin D supplementation trials (choosing target population, daily versus bolus dosing, choice of dosing, and compliance with supplementation regime are all potential confounders). However, as with other autoimmune disease, the possible use of vitamin D supplementation has the additional complication of *when* supplementation is most effective. As can be seen from sections earlier in this chapter, mechanistically it is likely that vitamin D is most effective in *preventing* the onset of autoimmune disease. However, any supplementation trial to address this would therefore require treatment of tens of thousands of healthy subjects to determine if the relatively small number of those subjects who develop autoimmune disease is diminished in those receiving vitamin D. This is particularly relevant if assessing the effects of vitamin D on disease risk for a specific autoimmune disorder such as RA, despite the fact that this is one of the more common autoimmune diseases. In this setting, the period of vitamin D supplementation to allow sufficient individuals to develop autoimmune disease and statistically assess possible effects of vitamin supplementation would be many years. Even if this was logistically possible, there are still likely to be complications with compliance and monitoring the effects of supplementation with respect to serum vitamin D status. It is therefore not surprising that, to date, most studies of vitamin D supplementation and RA have focused on investigating the effects of vitamin D supplementation on disease severity.

Table 103.2 shows a summary of the most prominent vitamin D supplementation trials in patients with RA. This illustrates the heterogeneity of the supplementation studies that have been reported so far. Some studies used early RA patients, others with sustained active

disease, and others with patients in remission. In some cases, patients were treatment naïve, while others involved patients receiving disease-modifying antirheumatic drugs (DMARDs). In a similar fashion, the mode of supplementation with vitamin D also varied. Weekly bolus dosing with 50,000 IU vitamin D<sub>3</sub> or higher doses was common, but other forms of vitamin D such as 1,25(OH)<sub>2</sub>D or alphacalcidol were also employed. Out of 12 studies shown in Table 103.2 that investigated effects of vitamin D supplementation, only 5 reported significant effects on disease severity, and this involved a variety of RA disease scores or markers. A 2020 systematic review of six studies from Table 103.2 [138,139,141,143,145,146] reported an overall significant improvement in DAS28, erythrocyte sedimentation rate (ESR), and tender joint score (TJC) with vitamin D supplementation but not for other markers of RA disease [166]. In selected subgroups and treatment durations, vitamin D supplementation did improve other markers of RA, and the overall conclusion was that vitamin D was an effective intervention for patients with RA [166]. It is also worth noting that in recent dietary recommendations, the French Society for Rheumatology stated that there was no indication for vitamin D (and other vitamins) for controlling the activity of chronic inflammatory rheumatic disease [167].

Of the 13 studies in Table 103.2, only 1 study to date has addressed the question of whether or not vitamin D supplementation provides protection against the onset of RA. The Vitamin D and Omega 3 Trial (VITAL) is a large-scale (25,871 subjects) vitamin D and omega fatty acid double-blind, placebo-controlled supplementation trial that was established to assess the effects of vitamin D<sub>3</sub> (2000 IU/day) and marine omega 3 fatty acids (1 g/day fish oil capsule with 460 mg eicosapentaenoic acid and 380 mg docosahexaenoic acid) in preventing cancer and cardiovascular disease [168] (see Chapter 78 for further details on this trial). A 5-year follow-up of VITAL showed a significant decrease in confirmed and probable autoimmune diseases in the vitamin D supplemented group, particularly after the initial 2 years of follow-up were excluded [148]. This observation was unaffected by cotreatment with omega fatty acids. The strengths of this study are the large number of participants and the extended period of supplementation adherence. However, a weakness of the study is that the number of subjects who developed autoimmune disease was small, and this prevented clear observations for individual autoimmune diseases. Nevertheless, for specific diagnosis of RA, there was a 40% reduction in those receiving vitamin D supplementation (15 versus 24 with RA from 12,927 to 12,944 subjects, respectively), and these data may improve with further follow-up [148]. Analysis of serum 25(OH)D levels in subsets of the trial participants showed an

increase from 29.8 ng/mL at baseline to 41.8 ng/mL after 1 year of vitamin D supplementation confirming that the supplementation regimen was sufficient to elevate serum vitamin D status. However, it is unclear if these elevated levels are maintained across the 5-year follow-up. More importantly, baseline levels of 25(OH)D of approximately 75 nmol/L indicate that the trial cohort was vitamin D sufficient even in the absence of the trial supplement (those in the placebo arm were allowed to continue routine vitamin D supplementation if less than 800 IU/day) [148]. It is tempting to speculate that a similar supplementation trial in participants with serum 25(OH)D levels less than 50 nmol/L at baseline might result in more significant effects in preventing autoimmune disease and RA in particular.

## 7. Conclusions

In common with other autoimmune diseases, there is a strong mechanistic link between vitamin D and the inflammation associated with RA. The synovial fluid and tissue of the inflamed joints of RA patients comprise an array of cells that can both synthesize 1,25(OH)<sub>2</sub>D from 25(OH)D, providing a link between vitamin D status (serum 25(OH)D levels) and the potential availability of 1,25(OH)<sub>2</sub>D within disease-affected tissues. The ability of this 1,25(OH)<sub>2</sub>D to direct a range of antiinflammatory, tolerogenic, and bone-sparing responses with these tissues means that vitamin D has the potential to act as a versatile suppressor of RA. Multiple association studies have endorsed this mechanistic rationale for vitamin D and RA by showing that low levels of serum 25(OH)D are associated with increased RA disease risk and severity. However, this is not necessarily evidence of a causative role for vitamin D deficiency in RA. Until recently, vitamin D supplementation trials had not shown any significant benefit in RA. However, the majority of these studies were focused on the impact of serum 25(OH)D levels on disease progression in established RA cases. Recent data from the VITAL supplementation trial suggest that enhanced 25(OH)D may be more effective in preventing RA. Bigger and much longer-term studies are needed to confirm the apparent protective effect of vitamin D in preventing diseases such as RA, but it also has to be recognized that the optimal serum level of 25(OH)D for good “immune health” (and prevention of autoimmune diseases) is still unclear. The potential benefits of vitamin D for existing RA patients also require a rethink. Can vitamin D be used alongside existing RA therapies? This possible strategy was endorsed by studies of the CD28 ligand blocker abatacept, which acts to block T cell activation in RA. Experiments in vitro showed that cotreatment with 1,25(OH)<sub>2</sub>D enhanced the efficacy of abatacept,

suggesting that vitamin D supplementation may be a useful adjunct for existing RA therapies [169]. It will be important for future studies to build on the existing wealth of information of vitamin D metabolism and function within the immune system to provide a better framework for the use of vitamin D in RA.

## 8. Summary points

- Intracrine and paracrine actions of 1,25(OH)<sub>2</sub>D by cells from the innate and adaptive immune system and by synovial fibroblasts are associated with potent systemic and synovial antiinflammatory responses.
- The T cell actions of 1,25(OH)<sub>2</sub>D are diminished in the memory T cells that predominate in the synovial fluid of joints.
- Low serum 25(OH)D is associated with increased risk of RA and increased risk of RA disease progression.
- Vitamin D supplementation trials have shown conflicting effects on RA disease risk and severity. However, recent data from the VITAL trial suggest a protective effect on risk of autoimmunity in older adults.

# Psoriasis and other skin disorders

Jörg Reichrath<sup>1,2</sup> and Michael F. Holick<sup>2</sup>

<sup>1</sup>The Saarland University Hospital, Homburg, Germany <sup>2</sup>Boston University School of Medicine, Boston, MA, United States

## OBJECTIVES

- To review the history of the use of vitamin D, 1,25-dihydroxyvitamin D<sub>3</sub>, and its analogs in dermatology.
- To provide the reader with an understanding of how 1,25-dihydroxyvitamin D<sub>3</sub> and its analogs can affect keratinocyte proliferation and differentiation.
- To review the physiology of the complex network regarding vitamin D metabolism and signaling in the skin.
- To review the clinical utility of 1,25-dihydroxyvitamin D<sub>3</sub> and its analogs for the treatment of psoriasis.
- To provide the reader with up-to-date information on the use of 1,25-dihydroxyvitamin D<sub>3</sub> and its active analogs for treating other autoimmune and hyperproliferative skin disorders.

## 1. Introduction/historical overview

Earlier in the past century, vitamin D<sub>3</sub> was used in dermatology in huge pharmacological doses for the treatment of scleroderma, psoriasis, lupus vulgaris, and atopic dermatitis. A rationale for the use of vitamin D in psoriasis was the clinical observation that this disease, in general, markedly improves in the summer. In 1936, J. Krafka wrote in *The Journal of Laboratory and Clinical Medicine* under the headline “A simple treatment for

psoriasis”: “A commonly observed fact in the South concerning this disease (psoriasis) is that it generally clears up in the summer sun. This led the author to the hypothesis that it might be cured with viosterol; irradiated ergosterol containing vitamin D<sub>2</sub>. A psoriasis patient with a case of 10 years standing, continuous duration was put on viosterol. Within 60 days from the beginning of the treatment, the skin of the patient was entirely clear” [1]. A year later, Ceder and Zon [2] reported 15 cases of widespread chronic psoriasis, 3 of whom had whole-body involvement. They were protected from sunlight as much as possible, and each patient received either 300,000–400,000 IUs of irradiated ergosterol or pure crystalline vitamin D<sub>2</sub> in sesame oil (50,000 IUs/capsule) orally daily. 10 of the 12 subjects who took the vitamin D<sub>2</sub> in sesame oil showed complete involution of their psoriasis within 6–12 weeks. Of the three patients, who took the irradiated ergosterol preparation, one showed complete involution and the other two obtained partial improvement within 10 weeks. All of the patients, except one, developed hypercalcemia ranging from 12 to 16 mg/dL. In 1950, Spier [3] reported results of a study with 94 psoriasis patients performed in 1948–49. First, patients received orally 3 × 10 mg vitamin D<sub>2</sub>/week for 2–4 weeks, thereafter 2 × 10 mg vitamin D<sub>2</sub>/week until a total dose of ~300 mg vitamin D<sub>2</sub> was reached. In this study, patients were treated for 3–4 month; 20% of patients showed a good response, 25% a satisfactory response, 25% a moderate response, and 30% a nonsatisfactory response [3].

But these first attempts of vitamin D treatment in dermatology were abandoned because of severe vitamin D intoxication that caused hypercalcemia, hypercalciuria, and kidney stones occurred when these huge pharmacological doses of vitamin D (up to 1000-fold of the

regular daily requirement of vitamin D) were used, and because other new treatments, including corticosteroids and retinoids, were introduced for the therapy of these diseases.

## 2. Pathogenesis of psoriasis

### 2.1 Psoriasis: Pathogenesis, immunology, and histology of skin lesions

Psoriasis is a chronic dermatosis of unknown etiology characterized by skin inflammation and hyperproliferation and altered differentiation of epidermal keratinocytes [4,5]. The most common form of the disease is plaque psoriasis, in which skin develops scaly, red lesions. The severity of chronic plaque psoriasis ranges from mild, when the disease has only a mild impact on quality of life, to severe, when patients' lives are significantly affected. In severe cases, most of the body surface, including the scalp and nails, may be involved. The peak age of onset for this psychologically debilitating and disfiguring disease is the second decade, but psoriasis may first appear at any age from infancy to the aged [6]. It is considered a multifactorial disease and has a prevalence of about 1%–2% in the United States. Population, family, and twin studies clearly demonstrate that there is a strong but very complex genetic component, leading to the development of psoriatic skin lesions [7]. Most likely, multiple genes are involved in the pathogenesis of psoriasis. During the past years, molecular biology techniques have been developed that allow studies to analyze psoriasis susceptibility genes, but up to today, no specific genetic marker of the disease is identified. Psoriasis has long been known to be associated with certain HLA antigens, particularly HLA-Cw6, although there is no evidence that a psoriasis susceptibility gene exists at this locus [8].

Until today, it is still not finally resolved what cell types in human skin are primarily affected by the disease. Many studies indicate that epidermal hyperproliferation in psoriasis is caused by cells of the immune system, most likely T lymphocytes [4]. The vast majority of T cells in psoriatic lesions are situated in the perivascular area in the dermis; a high number are also found in the epidermis. Activated CD4<sup>+</sup> and/or CD8<sup>+</sup> T cells in psoriatic lesions express HLA-DR, the interleukin (IL)-2 receptor (CD 25), bear the CLA + memory-effector CD45RO + phenotype, and secrete specific immune mediators and cytokines, such as IL-2 and interferon- $\gamma$  [9–46]. Thus, psoriasis represents mainly a so-called T helper 1 (Th1) profile disease (characterized by T lymphocyte secretion of IL-2, IL-12, and interferon- $\gamma$ ) [9]. In contrast, atopic dermatitis represents a so-called

Th2 profile disease that is characterized by T cell secretion of IL-4, IL-5, and IL-10 [10]. The activation signal for the development of psoriatic lesions is still unknown, although there is increasing evidence that superantigens such as the N-terminal component of bacterial M-proteins may be of importance for the initiation of T cell proliferation in psoriasis [4,9,11,47,48]. It has also been hypothesized that psoriasis patients develop an effector immune response to skin (auto) antigens, which are yet to be specifically identified. According to this model, the immunologic process underlying psoriasis begins with a sensitization-type phase during which the skin dendritic cells migrate to regional lymph nodes where they present these skin antigens to naïve T cells. This sensitization phase occurs prior to the development of skin lesions [11]. When sensitization is obtained, the psoriasis skin lesion may develop as a result of the emigration of T cells in the skin where they are activated by antigen-presenting cells (APCs) including Langerhans' cells presenting self-skin antigens [11].

The precise appearances of the histology of the skin will depend on the age of the psoriatic lesion and the site of the biopsy [12]. In general, epidermal hyperplasia, in which the granular layer may be lost, and the stratum corneum shows parakeratosis, can be found (Fig. 104.1). Typical lesions histologically will show elongation of the dermal papillae, with a relatively thin epidermis at the top of the papillae. The epidermis may show, in suprapapillary compartments, intercellular edema, and infiltration with T-lymphocytes and neutrophils, which can extend into spongiform pustules of Kogoj or Munro microabscesses [12].

### 3. The vitamin D system in normal and psoriatic skin

Vitamin D is photochemically synthesized by ultraviolet-B (UV-B) action in the skin [13–17] (also see Chapter 4 [vol. 1 of this book]). Alternatively, vitamin D<sub>2</sub> and D<sub>3</sub> can be supplemented by a balanced diet of sun-dried or UV-B-exposed mushrooms and animal origin including oily fish, cod liver oil, and foods that are fortified with vitamin D, respectively [17]. Many health agencies and scientific organizations highly recommend vitamin D supplementation to maintain bone health and reduce risk for many chronic illnesses including deadly cancers, autoimmune disorders, neurocognitive dysfunction, type 2 diabetes, and infectious diseases [18]. Vitamin D, whether produced in the skin from 7-dehydrocholesterol (7-DHC) or absorbed from the diet, is activated first in the liver to 25(OH)D and then in the kidneys to the classical biologically active metabolite 1,25(OH)<sub>2</sub>D<sub>3</sub> [17]. Notably, recent studies have revealed that a large number of other biologically

**FIGURE 104.1** Histological demonstration of morphological changes in lesional psoriatic skin after 6 weeks of topical treatment with calcitriol (15 µg/g, B) and calcipotriol (50 µg/g, C). (A) Lesional psoriatic skin before treatment. (D) Nonlesional psoriatic skin. Notice strong reduction of epidermal thickness after topical treatment with vitamin D analogs [74]. Hematoxylin–eosin staining. Original magnification  $\times 200$ .

active vitamin D metabolites can be synthesized and activated through a CYP11A1-driven noncanonical metabolic pathway and by other mechanisms [19–25]. It is known that the skin itself is a target tissue for vitamin D compounds, including the classical biologically active secosteroid hormone  $1,25(\text{OH})_2\text{D}_3$  [15–17].  $1,25(\text{OH})_2\text{D}_3$  binds to the vitamin D–binding protein (DBP, GC) in the circulation and is delivered to many target tissues, such as the intestine, bone, and kidneys, to regulate the calcium and phosphate homeostasis [17]. Moreover,  $1,25(\text{OH})_2\text{D}_3$  is also produced locally in many tissues including the epidermis and various immune cells [17], where it exerts autocrine or paracrine effects.

While  $1,25(\text{OH})_2\text{D}_3$  represents the classical biologically active vitamin D metabolite,  $25(\text{OH})\text{D}$  is the major (inactive) circulating form of vitamin D, commonly used as a serological indicator to evaluate the vitamin D status in patients [17,26]. In general, the functions of vitamin D analogs are characterized as genomic, i.e., mediated through vitamin D receptor (VDR)–mediated transcriptional effects inside the cell nucleus, and non-genomic, when VDR induces rapid signaling, including the ability to stimulate calcium transport across the plasma membrane [17,27,28]. To mediate its genomic effects,  $1,25(\text{OH})_2\text{D}_3$  binds to VDR with high affinity ( $K_D$   $10^{-9}$ – $10^{-10}$  M) and low capacity [18,19], which is present in many target tissues, including bone,

gastrointestinal tract, skeletal muscle, or skin [20], as well as in various immune cells, including dendritic cells, monocytes/macrophages, or lymphocytes [17]. Binding of its ligand  $1,25(\text{OH})_2\text{D}_3$  induces conformational changes that enables the VDR to form a heterodimer with retinoid x receptor (RXR) and to bind to vitamin D response elements (VDREs) in the genome to activate or suppress transcription of hundreds of genes in a cell-specific manner [21,22]. Nongenomic effects of  $1,25(\text{OH})_2\text{D}_3$  and analogs are, in part, related to effects on intracellular calcium [23,24]. In keratinocytes and other cell types,  $1,25(\text{OH})_2\text{D}_3$  rapidly increases free cytosolic calcium levels [23,24]. In the skin, both VDR (Fig. 104.2) and retinoid X receptor alpha ( $\text{RXR}\alpha$ ) are expressed in keratinocytes, fibroblasts, Langerhans cells, sebaceous gland cells, endothelial cells, and most cell types related to the skin immune system [17,20,25].

Apart from the classic role of vitamin D in the calcium and phosphate homeostasis, many *in vivo* studies have shown that active vitamin D metabolites additionally regulate a broad variety of other physiological processes, such as cell proliferation, differentiation, and immune modulation. Active vitamin D metabolites display immunomodulatory activity manifested by reduction in the APCs activity or proinflammatory T helper 1 (Th1) and T helper 17 (Th17) frequencies, as well as expansion of the T and B regulatory cells [26–29].

**FIGURE 104.2** Immunohistochemical demonstration of 1,25-dihydroxyvitamin  $\text{D}_3$  receptors (VDRs) in human skin. Notice strong nuclear VDR immunoreactivity in cells of all layers of the viable epidermis (arrows). Labeled avidin–biotin technique using mAb 9A7 $\gamma$  directed against VDR. Original magnification  $\times 400$ .

In addition, it has been reported that CYP11A1-derived vitamin D metabolites serve as ligands for VDR or can act as inverse agonists on retinoic acid receptor–related orphan receptors (ROR)  $\alpha$  and  $\gamma$  [30,31], which are known to play key roles in regulation of many immune and metabolic pathways. More recently, the top signaling pathways for CYP11A1-driven vitamin D analogs, such as  $20,23(\text{OH})_2\text{D}$ , were linked to activation of the aryl hydrocarbon receptor (AhR), and liver X receptors (LXR)  $\alpha$  and  $\beta$ , representing alternative receptors to VDR [32–36]. In this context, it has to be noted that despite the importance of UVB radiation for vitamin  $\text{D}_3$  synthesis, this optical radiation is also a key agent that induces DNA damage in the skin [37]. Both,  $1,25(\text{OH})_2\text{D}_3$  and CYP11A1-derived vitamin D analogs, protect epidermal keratinocytes against UVB-induced damage via activation of the Nrf2-dependent antioxidant response and p53-phosphorylation, as well as by induction of the DNA repair system [38]. In addition, both, the classical  $1,25(\text{OH})_2\text{D}_3$  and noncalcemic CYP11A1-driven analogs, exert antiinflammatory effects on keratinocytes by inhibiting the nuclear factor- $\kappa\text{B}$  (NF- $\kappa\text{B}$ ) activity [39,40].

*In vitro* studies have revealed that  $1,25(\text{OH})_2\text{D}_3$  is extremely effective in inducing the terminal differentiation and in inhibiting the proliferation of cultured human keratinocytes in a dose-dependent manner [41–43]. Additionally,  $1,25(\text{OH})_2\text{D}_3$  acts on many cell types involved in immunologic reactions, including lymphocytes, macrophages, and Langerhans cells (see Chapters 94–96). Data about the effects of  $1,25(\text{OH})_2\text{D}_3$  on the melanin pigmentation system are still conflicting, but most studies do not support that  $1,25(\text{OH})_2\text{D}_3$  regulates melanogenesis in human skin [44].

A study indicated that cutaneous mast cells may mediate their immunomodulatory effects at least in part via the VDR. In this investigation, biopsies were collected from the nonlesional and lesional skin of patients with actinic keratosis (AK), Bowen's disease/squamous cell carcinoma (SCC), basal cell carcinoma (BCC), and psoriasis. Expression of the metabolic enzymes, vitamin D-25-hydroxylase (CYP2R1, 25-OHase), and 25-hydroxyvitamin D- $1\alpha$ -hydroxylase (CYP27B1,  $1\alpha$ -OHase) in mast cells were analyzed by immunohistochemistry using a sequential double-staining method. The percentage of mast cells immunoreactive for CYP27A1 was significantly higher in lesional as compared with nonlesional skin in all diseases, especially in SCC and BCC. Moreover, the percentage of mast cells immunoreactive for CYP27B1 was significantly increased in BCC, AK, and psoriatic lesions as well. Only about 5%–6% and 2% of the mast cells expressed CYP27A1 and CYP27B1, respectively, in the nonlesional skin of psoriatic and AK patients. In contrast, 23%–38% and 6%–9% of the mast cells were

immunoreactive for CYP27A1 and CYP27B1, respectively, in the nonlesional skin of BCC and SCC patients. In human mast cell cultures, about 30% and 15% of the mast cells showed CYP27A1 and CYP27B1, respectively. The authors concluded that mast cells may promote an immunosuppressive environment, e.g., in skin carcinoma [45].

Sebocytes are sebum-producing cells that form the sebaceous glands. When the vitamin D endocrine system (VDES) in human sebocytes was analyzed recently, it was shown that sebocytes represent target cells for biologically active vitamin D metabolites [46]. It was demonstrated that human SZ95 sebocytes express VDR and the enzymatic machinery to synthesize and metabolize biologically active vitamin D analogs [46]. The expression of the VDR and the metabolic enzymes, CYP27A1, CYP27B1, and 1,25(OH)<sub>2</sub>D<sub>3</sub>-24-hydroxylase (CYP24A1, 24-OHase) were all detected in human SZ95 sebocytes in vitro using real-time quantitative polymerase chain reaction [46]. Although several other splice variants of 1 $\alpha$ -OHase were detected by nested touchdown polymerase chain reaction, it was demonstrated that the full-length product represents the major CYP27B1 gene product in SZ95 cells [46]. It was shown that incubation of SZ95 sebocytes with 1,25(OH)<sub>2</sub>D<sub>3</sub> resulted in a cell culture condition-, time-, and dose-dependent modulation of cell proliferation, cell cycle regulation, lipid content, and IL-6/IL-8 secretion in vitro, whereas RNA expression of VDR and

CYP24A1 was upregulated along with vitamin D analog treatment [46]. The authors concluded that the VDES is of high importance for sebocyte function and physiology and that sebaceous glands represent potential targets for therapy with vitamin D analogs or for pharmacological modulation of 1,25(OH)<sub>2</sub>D<sub>3</sub> synthesis and metabolism [46].

#### 4. Physiological and pharmacological actions of vitamin D analogs in normal and psoriatic skin

##### 4.1 Biological effects of vitamin D and analogs in psoriasis

The mechanisms underlying the therapeutic effectiveness of vitamin D analogs in psoriasis are still not completely understood. Results from immunohistochemical and molecular biology studies indicate that the antiproliferative effects of topical 1,25(OH)<sub>2</sub>D<sub>3</sub> on epidermal keratinocytes are more pronounced as compared with effects on dermal inflammation [49]. Modulation of various markers of epidermal proliferation (proliferating cell nuclear antigen and Ki-67 antigen) and differentiation (involucrin, transglutaminase K, filaggrin, cytokeratins 10,16) in lesional psoriatic skin after topical application of vitamin D analogs were shown in situ [49] (Fig. 104.3). Interestingly, effects of topical treatment with vitamin D analogs on dermal

**FIGURE 104.3** Immunohistological detection of transglutaminase K in lesional psoriatic skin before treatment (A), lesional psoriatic skin after 6 weeks of topical treatment with calcipotriol (50 µg/g, B), and in nonlesional psoriatic skin (C). Notice strong staining for transglutaminase K in all epidermal cell layers of lesional psoriatic skin before treatment (A, arrows). In contrast, after 6 weeks of topical treatment with calcipotriol staining in lesional psoriatic skin (B, arrows) is restricted to the upper layers of the viable epidermis, a staining pattern that is characteristic for nonlesional psoriatic skin (C, arrows). Original magnification  $\times 160$ .

inflammation are less pronounced (CD-antigens, cytokines, HLA-DR, etc.) as compared with effects on epidermal proliferation or differentiation. One reason for this observation may be that the bioavailability of this potent hormone in the dermal compartment may be markedly reduced as compared with the epidermal compartment [49].

However, some investigations demonstrate immune modulatory effects that may be of relevance for the therapeutic effectiveness of vitamin D analogs in psoriasis. Applying immunohistochemistry and flow cytometry, a study investigated in psoriasis lesions ( $n = 36$ ) of patients with chronic plaque psoriasis ( $n = 18$ ) the immunomodulatory effect of topical treatment with calcipotriol ( $50 \mu\text{g/g}$  vs. vehicle twice a day). After 14 days of treatment, no differences in the frequency of CD4(+) and CD8(+) T cells or innate lymphoid cells between calcipotriol- and vehicle-treated skin were found. No changes in the frequency of IL-22(+) or IFN- $\gamma$ (+) cells were observed. However, a significant decrease in CD8(+) IL-17(+) T cells in skin-derived cells from calcipotriol-treated skin was found, concomitant with clinical improvement, which was further supported by the absence of CD8(+)IL-17(+) T cells in immunohistochemical staining of calcipotriol-treated skin [50].

Interestingly,  $1,25(\text{OH})_2\text{D}_3$  and analogs have been shown to induce immunologic responses not only in conventional dendritic cells (cDCs) but also in plasmacytoid DCs (pDCs). pDCs comprise a specialized, naturally occurring DC subset known to be important in autoimmune diseases including psoriasis. pDCs from the blood rapidly infiltrate psoriatic skin and may represent a key to the initiation of the immune-mediated pathogenesis of the disease. Recently, it has been demonstrated that pDCs express key proteins of the VDES, including CYP27B1 and CYP24A1, and that VDR is transcriptionally active in pDCs. Moreover, vitamin D signaling impairs the capacity of murine and human pDCs to induce T cell proliferation and secretion of the T-helper 1 cytokine IFN $\gamma$ . This inhibitory effect is dependent on the expression of the VDR in the DCs. The authors concluded that vitamin D signaling can act as a natural inhibitory mechanism on both cDCs and pDCs, which may instigate the development of vitamin D-based therapeutic applications for psoriasis and other inflammatory skin diseases [51]. Some findings indicate that the immunomodulatory properties of vitamin D and analogs are mediated in part through effects on regulatory T cells (Treg). Mattozzi et al. [52] demonstrated an association of vitamin D status in psoriasis patients ( $n = 26$ ) with circulating Treg population ( $P < .001$ ) and with psoriasis area and severity index (PASI) score ( $P = .04$ ). The authors concluded that low serum levels of  $25(\text{OH})\text{D}$  may decrease the number of circulatory Treg, disrupting the immunological homeostasis in

psoriatic patients and encouraging the inflammatory activity [52].

Topically applied vitamin D compounds may induce effects on extracellular matrix (ECM) in psoriatic skin. Hyaluronan (HA), the major ECM component, is often anchored to CD44, a family of structurally/functionally important cell surface receptors. Both large HA polymers and their UVR-induced catabolic products (small HA) selectively activate CD44-mediated cellular signaling in human keratinocytes, with all of the downstream processes that include regulation of proliferation, differentiation, and inflammation being mediated by Rho GTPases (e.g., Rac1 and Rho). Interestingly, it has been reported that  $1,25(\text{OH})_2\text{D}_3$  not only prevents the UVR-induced small HA activation of abnormal keratinocyte behavior but also enhances large HA stimulation of keratinocyte activities and epidermal function(s). It was speculated that matrix HA and its UVR-induced catabolic products (e.g., large and small HA) can selectively activate CD44-mediated cellular signaling such as GTPase (Rac and RhoA) activation [53].

Cubillos et al. [54] investigated mechanisms that may underlie in part the efficacy of active vitamin D compounds in psoriatic arthritis. This study investigated osteoclast differentiation and cytokine secretion of peripheral blood mononuclear cells (PBMCs) from patients with psoriasis vulgaris and psoriatic arthritis, in response to  $1,25(\text{OH})_2\text{D}_3$ . Psoriatic arthritis patients had lower osteocalcin, as well as higher C-telopeptide of type I collagen and cathepsin K serum levels compared with psoriasis vulgaris patients and controls. Receptor activator of nuclear factor kappa-b ligand/macrophage-colony stimulating factor-stimulated PBMCs from psoriatic arthritis patients produced higher proinflammatory cytokine levels and had a differential secretion profile in response to  $1,25(\text{OH})_2\text{D}_3$ , compared with psoriasis vulgaris and control PBMCs. Interestingly,  $1,25(\text{OH})_2\text{D}_3$  abrogated altered bone turnover in psoriatic arthritis patients, and increased osteoclastogenic potential and proinflammatory cytokine secretion capacity of their PBMCs compared with psoriasis vulgaris and controls.

Molecular biology studies have demonstrated that clinical improvement in psoriatic lesions treated topically with  $1,25(\text{OH})_2\text{D}_3$  (calcitriol) correlates with an elevation of VDR mRNA [55]. It is well known that some patients suffering from psoriasis are resistant to topical  $1,25(\text{OH})_2\text{D}_3$  treatment. It was demonstrated that responders can be distinguished from the nonresponders at the molecular level because nonresponders show no elevation of VDR mRNA in skin lesions along with the treatment and express relatively low levels of VDR. These data suggest that the ability of calcitriol to regulate keratinocyte growth is closely linked to the expression of VDR. The target genes of topical

1,25(OH)<sub>2</sub>D<sub>3</sub> that are responsible for its therapeutic efficacy in psoriasis are still unknown. Major candidates for 1,25(OH)<sub>2</sub>D<sub>3</sub> target genes that are responsible for the 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced terminal differentiation in keratinocytes are distinct cell cycle-associated proteins (i.e., INK4 family), including p21/WAF-1 [56].

Visconti et al. [57] suggested a new role of VDR in the maintenance of the homeostasis of the skin barrier. Altered localization and formation of tissue junction proteins (that are crucial for the formation and maintenance of the paracellular barrier and for cell polarity in simple epithelia and endothelia) in the epidermis have been described in plaque-type psoriasis. An immunohistochemical study investigated the expression of VDR and tight junctions (TJ) proteins (claudin 1, ZO-1, and occludin) in psoriatic skin (n = 20). A reduction of VDR, claudin-1, and ZO-1 expression in psoriatic skin if compared with normal skin was observed, and the statistical analysis showed a significant correlation between a downgrading of VDR expression and that of claudin-1 ( $P < .005$ ) and ZO-1 ( $P < .005$ ). It was concluded that VDR status appears to be associated with the expression level and functions of TJ proteins, suggesting multiple and different cellular functions of the VDR.

Data analyzing VDR expression and genotype in psoriasis are somewhat conflicting [58–67], some studies report a correlation between VDR expression and individual VDR genotypes and the skin eruptions of psoriasis, as well as with responsiveness to treatment with vitamin D analogs. Although no differences in VDR genotype between controls and psoriasis patients were reported at the BsmI site, some studies reported significant difference in terms of ApaI SNP [60] and FokI SNP [61]. Additionally, it has been reported that VDR genotypes are not associated with clinical response to calcipotriol (a topical analog of 1,25(OH)<sub>2</sub>D<sub>3</sub> used in psoriasis) at least in Korean psoriasis patients [62]. Kontula et al. [63] and Mee et al. [64] studied the BsmI polymorphism and the response to calcipotriol treatment in psoriatic patients and found no association between them. According to Colin et al. [65], the FokI polymorphism was associated with the response to calcipotriol, and under conditions of vitamin D insufficiency, this finding might have clinical implications.

Richetta et al. [66] genotyped 108 patients with psoriasis and 268 healthy controls at 5 VDR polymorphisms (A-1012G, FokI, BsmI, ApaI, and TaqI) by TaqMan allelic-discrimination real-time polymerase chain reaction and found a significant increased overall risk of psoriasis for the VDR A-1012G promoter polymorphism (odds ratio [OR] = 2.43, 95% confidence interval [CI]: 1.15–5.13;  $P = .05$ ). A significant higher frequency ( $P = .035$ ) of the A allele was found in psoriatic cases compared with controls. In a case–case analysis, a

statistically significant association between A-1012G and family history emerged ( $P = .033$ ). Furthermore, a significant association of A-1012G risk genotypes with a lower expression of VDR mRNA emerged ( $P = .0028$ ). Results of this study indicated that VDR promoter A-1012G polymorphism is associated with psoriasis risk and suggest that this polymorphism may modulate psoriasis risk by affecting VDR expression.

A recent metaanalysis [67] that included a total of 16 studies with 2086 patients and 2182 controls on VDR polymorphisms and psoriasis indicated an association between psoriasis and the VDR TaqI TT genotype in Caucasian (OR = 1.29, 95% CI = 1.00–1.66,  $P < .05$ ), but not in Asian (OR = 1.32, 95% CI = 0.89–1.96,  $P = .16$ ) populations. However, no association was found between psoriasis and the VDR TaqI polymorphism using dominant, allele contrast or homozygous contrast models. Moreover, that study found no association between psoriasis and either the VDR ApaI, BsmI, or FokI polymorphisms by metaanalyses of the allele contrast, recessive, or dominant models or homozygous contrast models in the overall, Caucasian or Asian populations. The authors of that study concluded that polymorphisms in VDR ApaI, BsmI, and FokI are not associated with psoriasis susceptibility in overall, Caucasian or Asian populations. However, this study provides convincing evidence that VDR TaqI polymorphism is associated with psoriasis susceptibility in Caucasian populations.

As shown before, many association studies between psoriasis and VDR gene have been conducted to date, but the results are controversial. Moreover, the clinical response to the antipsoriatic activity of vitamin D<sub>3</sub> analogs has been reported to be variable. To solve these controversies, a study was conducted recently to explore whether VDR gene polymorphisms are associated with psoriasis susceptibility and clinical response to calcipotriol in psoriatic patients [68]. A total of 110 patients and 183 controls were genotyped for VDR gene polymorphisms rs2228570, rs731236, rs1544410, and rs7975232 by LDR method. SNP-based and haplotype-based association analyses were subsequently performed. Patients with PASI < 3 were treated with calcipotriol ointment monotherapy. After 6 weeks of therapy, the correlations between efficacy and the genotypes of each VDR polymorphism were evaluated. The results for rs7975232 demonstrated that allele A was significantly overrepresented in patients with psoriasis as compared with healthy controls (39.09% vs. 27.05%, OR (95% CI) = 1.731 (1.213–2.471)). Compared with the reference CC genotype, the following ORs were observed: AA genotype OR = 2.404 (95% CI: 1.085–5.328;  $P = .034$ ) and GA genotype OR = 2.143 (95% CI: 1.283–3.579;  $P = .005$ ). Haplotype analyses showed that the rs2228570/rs731236/rs1544410/

rs7975232 CTGA was significantly overrepresented in psoriasis patients compared with controls (OR (95% CI) = 1.907 (1.132–3.214);  $P = .020$ ). Analyzing patients with PASI < 3, the response rates to calcipotriol were significantly higher in patients with rs7975232 CC genotypes than in those with other genotypes ( $\chi^2 = 9.172$ ,  $P = .010$ ). In conclusion, results of this study suggest that VDR polymorphisms are associated with psoriasis susceptibility and clinical response to calcipotriol in psoriatic patients.

Data concerning serum levels of  $1,25(\text{OH})_2\text{D}_3$  or  $25(\text{OH})\text{D}$  in psoriatic patients are conflicting. Some studies report reduced levels of  $1,25(\text{OH})_2\text{D}_3$  in patients with manifest disease [69]. The interplay between vitamin D metabolites and the immunologic milieu in psoriatic skin has become of increasing interest. Psoriasis has been described as a prototypic Th17-mediated disease, and several reports highlight the relevance of an interplay between Th17 and  $1,25(\text{OH})_2\text{D}_3$  for the pathogenesis of this disease. Both factors appear to be entangled in analogous immunologic pathways, with IL-17 being proacanthotic, proinflammatory, and proangiogenic. Moreover, both appear to exert important opposing roles in innate and adaptive immunity, the interaction between which is considered to be of high relevance for the pathogenesis of psoriasis. Additionally,  $1,25(\text{OH})_2\text{D}_3$  has been shown to inhibit Th17 cell function, thereby suppressing its downstream cytokines, including IL-17. On the other hand, the reported decrease in total serum  $25(\text{OH})\text{D}$  levels has been suggested to be a result of the inflammatory milieu created by IL-17. The mean serum IL-17 was significantly higher ( $10.54 \pm 0.38$  pg/mL), and serum total  $25(\text{OH})\text{D}$  was significantly lower ( $21.05 \pm 3.66$  ng/mL) in psoriasis patients ( $n = 48$ ) than in age-, sex-, skin phototype-, and socioeconomic-matched controls ( $n = 40$ ) ( $P = .000$ ). No significant correlations were detected between IL-17 and serum  $25(\text{OH})\text{D}$  concentrations, or between IL-17 and  $25(\text{OH})\text{D}$  and any of the demographic or clinical data collected. These findings indicate a possible role played by Th17 cells and vitamin D insufficiency in the complex pathogenesis of psoriasis; however, their intertwined relationship has to be verified in future investigations [70]. Additionally, the coincidence of pustular psoriasis with hypocalcemia [71] and the exacerbation of psoriasis under chloroquine therapy (thereby reducing total  $1,25(\text{OH})_2\text{D}_3$  levels via inhibition of CYP27B1) are well known [72].

$1,25(\text{OH})_2\text{D}_3$  may also inhibit keratinocyte proliferation at least in part by upregulating leukocyte elastase inhibitor (serpin B1).  $1,25(\text{OH})_2\text{D}_3$ -treated and untreated HaCaT cells (multinucleated transformed keratinocytes) were separated by 2-D differential gel electrophoresis (2DE). Then, the 2DE profiles were analyzed to screen for differentially expressed proteins, which were

identified by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry. The upregulation of serpin B1 was confirmed by quantitative reverse transcription polymerase chain reaction (qRT-PCR) and Western blot analysis. The effect of serpin B1 on HaCaT proliferation was analyzed by RNA interference experiments, methylthiazolotetrazolium assay, and flow cytometry. Reproducible 2-DE profiles of HaCaT were established. It was observed that serpin B1 was upregulated in the  $1,25(\text{OH})_2\text{D}_3$ -treated cells that were confirmed by qRT-PCR and Western blot analysis.  $1,25(\text{OH})_2\text{D}_3$  inhibited proliferation of HaCaT cells at concentrations of  $10^{-9}$ – $10^{-6}$  mol/L. HaCaT cell proliferation was promoted when serpin B1 activity was inhibited. Serpin B1 was overexpressed in  $1,25(\text{OH})_2\text{D}_3$ -treated HaCaT cells and may play an important role in inhibiting HaCaT proliferation [73].

The synthetic  $1,25(\text{OH})_2\text{D}_3$  analog calcipotriol increases hCAP18 mRNA expression but inhibits extracellular LL37 peptide production in IL-17/IL-22-stimulated normal human epidermal keratinocytes [74]. Cathelicidin (LL37) serves as not only antimicrobial peptide but also as autoinflammatory mediator. Analogs, such as calcipotriol, are used as topical treatment for psoriasis. However, the effect of calcipotriol on the mRNA expression/production of human cathelicidin antimicrobial protein (hCAP18) and LL37 peptide by IL-17A/IL-22-stimulated keratinocytes remains controversial. To evaluate the modulatory action of calcipotriol on the production of hCAP18 and LL37, hCAP18 mRNA expression was analyzed as well as hCAP18/LL37 peptide production in IL-17A/IL-22-stimulated cultured human keratinocytes by real-time qPCR, ELISA, Western blotting, and immunocytochemistry. By Western blotting, hCAP18 protein was detected in keratinocytes cultured for 72 hours with IL-17/IL-22. Calcipotriol increased hCAP18 mRNA expression in IL-17/IL-22-stimulated keratinocytes. However, LL37 peptide in the culture supernatants was reduced by calcipotriol. Immunostaining revealed that the overproduced LL37 resides within the cells. LL37 promotes psoriasis via interaction with extracellular DNA but may suppress psoriasis by interfering with cytosolic DNA.

## 5. Clinical use of $1,25(\text{OH})_2\text{D}_3$ and its analogs in psoriasis and other skin diseases

The use of  $1,25(\text{OH})_2\text{D}_3$  and its analogs for the treatment of psoriasis resulted from two independent lines of investigation. Because psoriasis is a hyperproliferative skin disorder, it seemed reasonable that the antiproliferative effects of  $1,25(\text{OH})_2\text{D}_3$  could be used for the treatment of this disease. Although it was known that  $1,25(\text{OH})_2\text{D}_3$  was extremely potent in inhibiting

keratinocytes proliferation before launching clinical trials in 1985, MacLaughlin and associates reported the observation that psoriatic fibroblasts were partially resistant to the antiproliferative effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> [75]. This observation prompted MacLaughlin and associates to speculate that 1,25(OH)<sub>2</sub>D<sub>3</sub> may be effective in the treatment of the hyperproliferative skin disease psoriasis if pharmacologic doses were employed. The other line of investigation resulted from a clinical observation. In 1985, Morimoto and Kumahara reported that a patient, who was treated orally with 1 $\alpha$ (OH)D<sub>3</sub> for osteoporosis, had a dramatic remission of psoriatic skin lesions [76]. Morimoto et al. reported a follow-up study, demonstrating that almost 80% of 17 patients with psoriasis who were treated orally with 1 $\alpha$ (OH)D<sub>3</sub> at a dose of 1.0  $\mu$ g/day for up to 6 months showed clinically significant improvement [77].

Currently, numerous studies have reported that various vitamin D analogs, including calcitriol, calcipotriol, tacalcitol, hexafluoro-1,25(OH)<sub>2</sub>D<sub>3</sub> [78], and maxacalcitol, are effective and safe in the topical treatment of psoriasis [79–87]. It has been shown that topical calcitriol and its analogs are very effective and safe for the long-term treatment of psoriasis [84–86]. Applied twice daily topically in amounts of up to 100 g of ointment (50  $\mu$ g calcipotriol/g ointment) per week, calcipotriol was shown to be slightly more effective in the topical treatment of psoriasis than betamethasone 17-valerate ointment [86]. Efficacy of topical treatment with maxacalcitol was compared with topical calcipotriol treatment [82]. In this study, investigators' overall assessment suggests that maxacalcitol 25  $\mu$ g/g may be more effective than once-daily calcipotriol (50  $\mu$ g/g). It has been reported that a mild dermatitis can be seen in about 10% of patients treated with calcipotriol (50  $\mu$ g/g), particularly on the face [87]. This side effect (mild dermatitis on the face) is not reported after topical treatment with calcitriol. Allergic contact dermatitis to vitamin D analogs is very rare; however, cases with allergic contact dermatitis to other ingredients of the ointment including propylene glycol have been reported [88–90]. The most common adverse event observed in psoriasis patients treated with maxacalcitol (6–50  $\mu$ g/g maxacalcitol ointment) was a burning sensation of the target plaque [82]. In three out of four patients developing this side effect in one study, symptoms were severe enough to require discontinuation of the treatment [82].

A double-blind, right/left comparison, placebo-controlled evaluation demonstrated efficacy and safety of topical treatment with hexafluoro-1,25(OH)<sub>2</sub>D<sub>3</sub> (5  $\mu$ g/g) in psoriasis patients [83]. Adverse events included mild irritation. This irritation did not necessitate discontinuation of the study medication. During the large area topical administration study period, a

cobblestone appearance was initially noted in a few patients. This resolved with continued therapy after 3–4 weeks. Hexafluoro-1,25(OH)<sub>2</sub>D<sub>3</sub>-treated plaques also developed very mild perilesional scales as observed with other vitamin D analogs [83]. Efficacy and safety of topical treatment with tacalcitol (4 and 20  $\mu$ g/g) has been shown as well [83–85,91]. In one study, tacalcitol treatment was generally well tolerated, and there were no serious or unexpected adverse events reported. However, discontinuation of treatment as a result of skin irritation was seen in 5.9% of these patients [85]. The greatest frequency of cutaneous side effects occurred during initial treatment, and the incidence decreased markedly as the treatment was well tolerated with continued use [85].

The results of four separate studies designed to evaluate specific local-safety parameters of various vitamin D analogs including cumulative irritancy, cutaneous contact sensitization, photoallergic contact sensitization, and phototoxicity, were analyzed [92]. 1,25(OH)<sub>2</sub>D<sub>3</sub> (3  $\mu$ g ointment) was classified as nonirritant when compared with calcipotriol, tacalcitol, and white petrolatum (control). Petrolatum and tacalcitol were slightly irritant and calcipotriol moderately irritant. No sensitization was observed with 1,25(OH)<sub>2</sub>D<sub>3</sub> (3  $\mu$ g ointment). Regarding phototoxic potential, sites treated with calcitriol 3  $\mu$ g ointment or vehicle ointment were less irritated than those treated with white petrolatum or those that were untreated. Using standard photoallergenicity testing methodology, there were no skin reactions of a photoallergic nature to the study material [92].

A long-term follow-up study demonstrated the efficacy and safety of oral calcitriol as a potential treatment of psoriasis [93]. Of the 85 patients included in that study that received oral calcitriol for 36 months, 88.0% had some improvement in their disease, whereas 26.5%, 26.3%, and 25.3% had complete, moderate, and slight improvement in their disease, respectively. Serum calcium concentrations and 24 hours urinary calcium excretion increased by 3.9% and 148.2%, respectively, but were not outside the normal range. Bone mineral density of these patients remained unchanged. A very important consideration for the use of orally administered calcitriol is the dosing technique. To avoid its effects on enhancing dietary calcium absorption, it is very important to provide 1,25(OH)<sub>2</sub>D<sub>3</sub> at night time. Perez et al. [93] showed that as a result of this dosing technique, doses of 2–4  $\mu$ g/night 1,25(OH)<sub>2</sub>D<sub>3</sub> are well tolerated by psoriatic patients.

In the 1930s, very high doses of vitamin D were found to be very effective in treating psoriasis [1–3]. However, due to severe toxicity, this practice was halted. Coimbra and colleagues resurrected high-dose vitamin D therapy and avoided severe hypercalcemia by placing their patients on a zero-calcium diet [94]. They reported 9

patients with extensive plaque psoriasis on 35,000 IUs of vitamin D<sub>3</sub> daily for 6 months. These patients were on a strict low-calcium diet avoiding dairy products and calcium-enriched foods with good hydration of at least 2.5 L of water daily. They demonstrated dramatic improvement in the Psoriasis Area and Severity Index (PASI) score for all 9 patients. They reported that the mean baseline 25(OH)D was  $18.4 \pm 8.9$  ng/mL, and at the end of the trial the concentration was  $106.3 \pm 31.9$  ng/mL. They reported that the serum concentrations of PTH significantly decreased from  $57.8 \pm 16.7$  to  $28.9 \pm 8.2$  pg/mL, and there was no significant change in the serum calcium concentrations ( $9.7 \pm 0.7$  baseline and 6 months later  $9.4 \pm 0.7$  mg/dL) [94]. Recently, Mahtani et al. [95] using the Coimbra protocol reported 6 cases of psoriasis treated with daily oral vitamin D<sub>3</sub> in doses ranging from 30,000 IU to 60,000 IU over a period of 2–6 months and then followed by lower daily maintenance doses were reported. The dose of vitamin D<sub>3</sub> was adjusted based on the drop in the level of parathyroid hormone as the ionized calcium levels were also periodically monitored to prevent hypercalcemia. The rationale for this treatment with relatively high doses of vitamin D was the growing body of evidence published in the scientific literature suggesting that vitamin D<sub>3</sub> resistance caused by polymorphisms in genes that contribute to vitamin D metabolism may have a potential role in the pathoprogenesis of psoriasis. Notably, complete control of psoriasis was observed within a span of 2–6 months, which was assessed by PASI and a symptom Visual analog scale. The authors concluded that supervised, daily oral higher than usual vitamin D<sub>3</sub> can be given safely as an effective therapeutic modality for treating psoriasis [95].

Patients with psoriasis may need intermittent treatment for their entire lives. Vitamin D analogs have been shown not to exhibit tachyphylaxis during treatment of psoriatic lesions, and topical treatment can be continued indefinitely.

### 5.1 Treatment of scalp psoriasis

A double-blind, randomized multicenter study demonstrated that calcipotriol solution is effective in the topical treatment of scalp psoriasis [96–98]. 49 patients were treated twice daily over a 4-week period [96]. 60% of patients on calcipotriol showed clearance or marked improvement versus 17% in the placebo group. No side effects were reported.

### 5.2 Treatment of nail psoriasis

The occurrence of nail psoriasis has been reported in up to 50% of patients. Nails, in general, are very difficult

to treat and respond slowly. Until now, there has been no consistently effective treatment for psoriatic nails. It has been reported that calcipotriol ointment is effective in the treatment of nail psoriasis [99].

### 5.3 Treatment of face and flexures

Although the use of calcipotriol ointment is not recommended on face and flexures because of irritancy, most patients tolerate vitamin D analogs on these sites. It has been shown that calcitriol ointment (3 µg of 1,25(OH)<sub>2</sub>D<sub>3</sub> per gram of petrolatum) was found to be better tolerated and would appear to be more effective than calcipotriol ointment (50 µg of calcipotriol per gram of petrolatum) in the treatment of psoriasis in sensitive areas [100].

### 5.4 Treatment of skin lesions in children

During the past few years, it has been shown that topical application of vitamin D analogs including calcitriol ointment (3 µg of 1,25(OH)<sub>2</sub>D<sub>3</sub> per gram of petrolatum) is an effective, safe, and reliable therapy to cure psoriatic skin lesions in children [101–103].

### 5.5 Treatment of psoriatic lesions in HIV patients

We have treated an HIV-positive patient suffering from psoriatic skin lesions with topical and oral 1,25(OH)<sub>2</sub>D<sub>3</sub>. The patient responded well, and there was no evidence of enhancement in HIV-disease activity or alterations in the number of T lymphocytes, or CD4<sup>+</sup>, and CD8<sup>+</sup> cells.

### 5.6 Combination of vitamin D analogs with other therapies

It has been reported that efficacy of topical treatment with vitamin D analogs in psoriasis can be increased by combination with other therapies, including methotrexate (MTX), very-low-dose oral cyclosporine (2 mg/kg/day), oral acitretin, topical dithranol, topical steroids, PUVA (psoralen plus UV-A) and UV-B, or narrow band UV-B phototherapy [104–112]. It has been shown that the combination of calcipotriol and MTX is safe and well tolerated [111]. The combination resulted in lower cumulative dosages of MTX compared with MTX and vehicle. Therefore, the risk of MTX-induced side effects is substantially decreased [111]. Addition of calcipotriol ointment to oral application of acitretin (a vitamin A analog) was shown to produce a significantly better treatment response achieved with a lower cumulative dose of acitretin in patients with severe

extensive psoriasis vulgaris, as compared with the group of patients treated with oral acitretin alone. The number of patients reporting adverse events was similar between the two treatment groups [106].

Complete clearing or 90% improvement in PASI was observed in 50% of patients treated with calcipotriol/cyclosporine versus 11.8% in the placebo/cyclosporine group. No difference was found in that study between the groups in short-time side effects. Kragballe and co-workers reported that efficacy of topical calcipotriol treatment in psoriasis can be improved by simultaneous UV-B phototherapy. Combination therapy of psoriasis with topical calcipotriol and narrow-band UV-B has been shown to be very effective for the treatment of psoriatic plaques [108]. One can speculate whether the therapeutic efficacy of UV-B in psoriasis may be at least in part because of increased cutaneous vitamin D synthesis. It has been shown that the combination of topical treatment with vitamin D analogs and UV-radiation does not alter the tolerability or safety of therapy [113]. Vitamin D analogs may be topically applied at any time up to 2 hours before or immediately after UV radiation [102]. Results of a controlled, right/left study have demonstrated that pretreatment of psoriasis with the vitamin D<sub>3</sub> derivative tacalcitol increases the responsiveness to 311-nm UV-B [114]. Additionally, it was shown that tacalcitol ointment (4 µg/g) and 0.1% tazarotene gel are both comparably effective in improving the therapeutic result of PUVA therapy in patients with chronic plaque-type psoriasis [115]. The treatment requirements to induce complete or near complete clearing were significantly lower for both combination treatments than for PUVA monotherapy ( $P < .01$ ). The median cumulative UV-A dose and number of exposures were 30.6 J/cm<sup>2</sup> (95% CI 22.5–71.2) and 14 (95% CI 11–16) for tacalcitol plus PUVA, 32.3 J/cm<sup>2</sup> (95% CI 22.5–73.8) and 14 (95% CI 11–19) for tazarotene plus PUVA, and 37.0 J/cm<sup>2</sup> (95% CI 29.5–83.9) and 16 (95% CI 14–22) for PUVA monotherapy. No difference between the three regimens was observed with regard to duration of remission. Adverse reactions occurred more often with 0.1% tazarotene than with tacalcitol but were, in general, mild and completely reversible on using a lower concentration of 0.05% tazarotene. It has been concluded that besides accelerating the treatment response, both agents, by virtue of their UV-A dose-sparing effect, might also help to reduce possible long-term hazards of PUVA treatment. Previously, a case report described two patients treated with a combination treatment of calcipotriol and bath psoralens and UV-A who developed hyperpigmentation at the lesional sites where calcipotriol ointment was applied [116].

Combined topical treatment with calcipotriol ointment (50 µg/g) and betamethasone ointment was shown to be slightly more effective and caused less skin irritation than calcipotriol used twice daily [107]. A vehicle has been created with the objective of obtaining optimal stability of both calcipotriene and betamethasone dipropionate in the combination product. Early onset of action and efficacy of a fixed combination of calcipotriene and betamethasone dipropionate in this vehicle in the treatment of psoriasis has been reported, making it a standard therapy for the topical treatment of psoriasis [117].

Augustin et al. [118] evaluated scientific evidence about topical long-term therapy with 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs, corticosteroids, and their two-compound products in psoriasis vulgaris and scalp psoriasis and developed daily practice recommendations. Best evidence regarding topical long-term treatment was available for the two-compound formulation containing calcipotriene and betamethasone. In a comparative trial in psoriasis vulgaris, the two-compound formulation showed superior tolerability and cost-effectiveness compared with monotherapy. In scalp psoriasis, the two-compound gel was superior compared with calcipotriene monotherapy. The authors concluded that because of a favorable risk–benefit ratio in maintenance trials and better cost-effectiveness, the application of two-compound products once or twice a week after initial therapy is recommended. It has been hypothesized that calcipotriol counteracts glucocorticoid-induced skin atrophy, which is associated with changes in the ECM. To elucidate the combined effects of calcipotriol and betamethasone on key ECM components, a comparative study to the respective monotreatments was carried out. The effect on collagen I synthesis, matrix metalloproteinase (MMP) secretion, and hyaluronic acid (HA) production was investigated in primary human fibroblast and keratinocyte cultures as well as in a human skin explant model. In that study, calcipotriol counteracted betamethasone-induced suppression of collagen I synthesis. Similarly, calcipotriol and betamethasone had opposing effects on MMP expression in both fibroblasts and keratinocytes. Moreover, calcipotriol was able to restore betamethasone-impaired HA synthesis in keratinocytes and prevented betamethasone-induced epidermal thinning in minipigs on treatment with a calcipotriol/betamethasone gel. In summary, these results showed for the first time in primary human skin cultures that calcipotriol reduces early signs of betamethasone-induced skin atrophy by modulation of key ECM components. These results indicate that the calcipotriol component of the fixed combination gel counteracts the atrophogenic effects of betamethasone on the skin [119].

## 6. Vitamin D in prevention and therapy of other skin diseases

### 6.1 Ichthyosis

A double-blind, bilaterally paired, comparative study has demonstrated the effectiveness of topical treatment with calcipotriol ointment on congenital ichthyoses [120]. Reduction in scaling and roughness on the calcipotriol-treated side was seen in all patients with lamellar ichthyosis and bullous ichthyotic erythroderma of Brocq. The only patient treated with Comel-Netherton syndrome showed mild improvement, whereas the only patient suffering from ichthyosis bullosa of Siemens who was treated with calcipotriol did not show any change in severity on the calcipotriol-treated as compared with the vehicle-treated side. It has been reported that topical tacalcitol therapy was ineffective against ichthyoses that are characterized by retentive hyperkeratosis and a lack of epidermal hyperproliferation, including X-linked ichthyosis, ichthyosis vulgaris, and acquired ichthyosis [121].

Although the use of various active vitamin D analogs for treating various forms of ichthyosis has proven to be somewhat effective, short-term high-dose vitamin D in children with congenital ichthyosis was reported to be very effective. Seven children with congenital ichthyosis (five with the autosomal recessive congenital ichthyosis; two with epidermolytic ichthyosis) who were severely vitamin D deficient and had rickets were given 60,000 IUs vitamin D<sub>3</sub> daily for 10 days. The children were then placed on 400–600 IUs daily. The authors reported significant improvement in scaling by day 5, showing further improvement by day 10 in 6 of the 7 cases. At 1 month, the skin had become nearly normal in all cases of autosomal recessive congenital ichthyosis. Significant reduction in stiffness was also observed in all of the children [122].

### 6.2 Scleroderma

Preliminary findings point to the efficacy of vitamin D analogs for the treatment of scleroderma. Humbert et al. [123] reported that oral administration of 1.0–2.5 µg/day calcitriol improves skin involvement, probably via inhibition of fibroblast proliferation and dermal collagen deposition. Notably, it was recently demonstrated that several vitamin D hydroxyderivatives, including noncalcemic 20(OH)D<sub>3</sub>, generated by CYP11A1 action on vitamin D<sub>3</sub>, exert antifibrotic activity in human dermal fibroblasts and in a bleomycin-based mouse model of scleroderma [124]. In that study, it was shown that the antiproliferative and antifibrotic activities of these vitamin D hydroxyderivatives depend on the functional integrity of retinoic orphan

receptor (RORγ). In that study, all vitamin D analogs tested inhibited TGF-β1-induced collagen synthesis in RORγ+/+ fibroblasts and the expression of other fibrosis-related genes. Notably, this effect was curtailed or reversed in RORγ–/– fibroblasts. Treatment with 20(OH)D<sub>3</sub> or 1,20(OH)<sub>2</sub>D<sub>3</sub> exerted strong changes in the transcriptomes of fibroblasts of RORγ–/– versus wild-type mice were seen. The authors concluded that these findings provide a molecular basis to explain, at least in part, the observed phenotypic differences [124].

### 6.3 Vitamin D and autoimmune bullous diseases of the skin

Many epidemiological studies have linked vitamin D deficiency to an increased risk for the development of various autoimmune diseases, including diabetes mellitus type 1, rheumatoid arthritis, inflammatory bowel disease, multiple sclerosis, or systemic lupus erythematosus. More recently, such a connection was also proposed for several skin autoimmune diseases, including autoimmune bullous diseases (AIBD). AIBD represents a group of relatively rare and potentially life-threatening chronic inflammatory skin diseases, which can be categorized into three different subgroups, namely pemphigus vulgaris (PV), bullous pemphigoid (BP), and dermatitis herpetiformis (DH), which are all characterized by the presence of many different tissue-bound and circulating autoantibodies. Dermatitis herpetiformis represents the cutaneous manifestation of celiac disease with autoantibodies directed against the tissue and the epidermal transglutaminase [125]. The term pemphigus comprises a group of autoantibody-mediated autoimmune diseases in which the loss of cell adhesion (acantholysis) can cause blisters and erosions in the skin and mucosa. There are two major subtypes of pemphigus diseases, its most common form pemphigus vulgaris (PV) and pemphigus foliaceus (PF), characterized by the presence of autoantibodies directed against cell–cell adhesion molecules found in desmosomes in the epidermis, namely desmoglein (Dsg) 1 and desmoglein 3 [126]. Bullous pemphigoid (BP), characterized by autoantibodies to BP180 (collagen type XVII or COL17) and BP230, is the most common autoimmune subepidermal blistering disorder, whose incidence, similarly to other autoimmune diseases, is constantly increasing [125]. By contrast, epidermolysis bullosa acquisita (EBA), a subepidermal blistering disease with autoantibodies to type VII collagen (COL7), is one of the rarest AIBDs, with an incidence rate of 0.2–0.5 per million per year [127].

While the etiology of pemphigus diseases and BP is mostly unknown, several genetic and environmental

risk factors have been proposed. PV, PF, and BP all are frequently associated with other (auto) inflammatory diseases, such as psoriasis, neurological and psychiatric disorders, or some malignancies. In the case of PV, genetic risk factors include either HLA alleles DRB1\*04:02 and DQB1\*05:03 or non-HLA genes, i.e., DSG3, TAP2, IL6, and ST18. In addition, an association between HLA-DQB1\*0301 and BP or mucous membrane pemphigoid (MMPem), as well as the risk allele HLA-DRB1\*15:03 or association between HLA-DR2 and EBA, were reported [128,129]. In PV, environmental risk factors, in particular use of penicillamine and captopril, as well as exposure to pesticides, metal vapor, UV, ionizing radiation, burns, undergoing surgery or stressful life events, have been noted. For BP, several environmental or genetic risk factors, including trigger factors, such as penicillin, vancomycin, gentamycin, trauma, burns, radiotherapy, UV radiation, vaccination, and contact allergy to metals, have been described [127,128]. The majority of studies investigating the pathophysiology of pemphigoid are based on experimental animal models and numerous evidence pointed to pathogenic importance of both the local and systemic innate and adaptive autoimmune responses against structural proteins of the dermal–epidermal junction [128,129].

In genetically susceptible individuals, the autoimmune reaction is driven by autoreactive T and B lymphocytes. Autoreactive T cells are educated by APCs that present Dsg peptides via HLA class II molecules. Consequently, autoreactive T helper cells specific for Dsg molecules drive generation of autoreactive B cells and secretion of the tissue-bound and circulating autoantibodies to Dsg [126,130].

Pemphigus can be treated with systemic corticosteroids and adjuvant therapies, including immunosuppressive agents, intravenous immunoglobulin (IVIG), and plasmapheresis. In addition, rituximab, a monoclonal antibody against the CD20 molecule (B cells' marker), is another promising therapeutic option [126]. As in the case of PV, BP can be controlled medically by using corticosteroids, high doses of IVIG, rituximab, plasmapheresis, and immunoadsorption [128,131].

### 6.3.1 Vitamin D status in autoimmune bullous diseases

In recent years, the role of vitamin D has been investigated in AIBD [29,40,132–143], and emerging evidence suggests an increased frequency of vitamin D deficiency/insufficiency in patients with pemphigus and pemphigoid, such as the PV and BP or EBA, respectively. In addition, in some reports, lower concentrations of 25(OH)D have been associated with AIBD activity, pointing toward a possible causative role of hypovitaminosis D in the disease process [132,133,142]. However, some other studies have found no difference in the

25(OH)D levels between patients and healthy subjects, possibly due to limited number of patients and controls involved in these studies [136,140,143].

### 6.3.2 Experimental therapies using vitamin D analogs in autoimmune bullous diseases

While patients with the autoimmune bullous skin diseases suffer from vitamin D deficiency [29,40,132–143], a causal relationship between hypovitaminosis D and the development of autoimmune bullous diseases has not been proven. It is hypothesized that binding of BP-specific IgG autoantibodies to BP180 initiates the Fc receptor-independent events, leading to the excessive expression and secretion of proinflammatory IL-6 and IL-8 from basal keratinocytes [128,144]. Activation of complement at the dermal–epidermal junction (DEJ), together with the mast cells' degranulation and inflammatory chemokines, results in the infiltration of inflammatory cells, including granulocytes, in the upper dermis. The reactive oxygen species (ROS) and matrix metalloproteinases (MMP) released by the activated granulocytes induce dermal–epidermal splitting and blister formation [128]. It was reported that BP IgG-induced IL-6 and IL-8 secretion from human keratinocytes HaCaT cells was reduced in the presence of calcitriol via inhibition of STAT3 phosphorylation and NF- $\kappa$ B activity [40]. Effectiveness of the calcitriol treatment was confirmed in vivo by using a well-established EBA mouse model, which offers an elegant tool to study the pathogenesis of autoantibody-induced and immune cell-mediated blistering, as well as enables investigators to identify new therapeutic targets for EBA and other AIBD [129,145]. It was found that orally administrated calcitriol modulated the clinical course of experimental EBA through induction of the T and B regulatory cells, as well as downregulation of neutrophil activity and blockade of proinflammatory Th17 cell population [29]. Because both, the immunosuppressive Treg and Breg, or proinflammatory Th1, Th17, and neutrophils are associated with the AIBD development [29,146–150], targeting these cell populations is an important therapeutic approach in AIBD.

In conclusion, despite growing understanding of AIBD pathogenesis, treatment of this group of rare skin disorders remains challenging. This is because of frequent relapses, numerous side effects due to corticosteroid usage, or simply due to lack of effective treatment [131,151]. In addition, the incidence of AIBD is constantly increasing [125], and therefore, there is a growing urgency for discovering an effective treatment or prophylactic regimen to reduce the incidence of these autoimmune disorders. Despite the usage of topical vitamin D analogs in the treatment of autoimmune skin conditions, such as psoriasis and vitiligo [141,152], there are only a limited number of

epidemiological and experimental studies on vitamin D involvement in autoimmune bullous diseases. This emerging topic requires further research including clinical trials investigating the effect of topically or systemically applied pemphigus and pemphigoid patients. In fact, several case reports have described the efficacy of either orally or topically applied vitamin D analogs [135,138,153] in Hailey–Hailey disease, also known as a familial benign chronic pemphigus. Finally, because there are many case reports describing the coexistence of AIBD and psoriasis [154], the role of topically applied vitamin D analogs in the treatment of these disorders needs to be properly evaluated.

#### 6.4 Vitamin D and hair diseases

Hair diseases, presenting with scarring or nonscarring hair loss, are a common problem that affects both male and female patients [155,156]. Since any disturbances in the cycling of hair follicles may lead to hair shedding, or alopecia, and considering the pluripotent biologic effects of vitamin D compounds, it is not surprising that the relevance of vitamin D for hair diseases was investigated in many studies. The role of VDR has been well established and extensively studied in the hair cycle. Its deficiency is also closely linked to several types of alopecia, including alopecia areata, telogen effluvium, and androgenetic alopecia (AGA). The scientific rationale why vitamin D derivatives may represent promising candidates to prevent and to treat hair disorders and diseases is based on the ability of these compounds to regulate many cellular mechanisms that are of importance for hair growth, including their anti-inflammatory and immunomodulatory properties and their ability to regulate keratinocyte differentiation and proliferation. Moreover, the expression of the VDR was shown in key structures of the hair follicle, making them to targets of vitamin D activity. In line with these findings, it was shown that vitamin D hydroxyderivatives regulate the hair cycle, and their role in hair loss is under constant research. A recent systematic review summarized our present scientific knowledge how the vitamin D endocrine system regulates many of the various signaling pathways that affect growth and differentiation of hair follicles. Notably, vitamin D deficiency was in that study also associated with scarring alopecia.

Most studies included into that review showed an inverse relationship between serum 25(OH)D levels in patients with different types of nonscarring alopecia, which could suggest a contribution of the vitamin D endocrine system to the pathogenesis of hair loss and nonscarring alopecias including telogen effluvium, androgenetic alopecia (AGA), alopecia areata, and

trichotillomania. Gerkowicz et al. [155] review of the literature (searching PubMed and Google Scholar databases) identified 13 relevant articles with a focus on AGA, male pattern baldness, and serum 25(OH)D levels [157]. The authors concluded that serum vitamin D status might be a possible parameter for diagnosing the onset and severity of AGA. They report that vitamin D supplementation has proven to be useful in the regrowth of hair in nonhuman subjects. In their opinion, oral vitamin D supplementation or topical application of vitamin D compounds may therefore represent a valid therapeutic approach in many hair diseases including androgenetic alopecia, where topical calcipotriol has been suggested to be a promising treatment option to regrow hair follicles and prevent miniaturization of follicles.

To clarify the association of alopecia areata (AA) with serum vitamin D status and calcium levels, a systematic review and metaanalysis [158] investigated recently all relevant articles published up to February 2020 in PubMed, Embase, and Cochrane Library databases. Data on 1585 patients with AA and 1114 controls from 16 case–control studies and three cross-sectional studies were included in this pooled metaanalysis that was conducted using the random-effects model because of interstudy heterogeneity (vitamin D level,  $I^2 = 87.90\%$ ; vitamin D deficiency,  $I^2 = 81.10\%$ ; serum calcium level,  $I^2 = 83.80\%$ ). A combined analysis revealed that patients with AA had significantly lower mean serum 25(OH)D levels compared with controls (WMD  $-9.08$ , 95% CI  $-11.65$ ,  $-6.50$ ,  $P < .001$ ) and were more likely to have vitamin D deficiency (OR 4.14, 95% CI 2.34, 7.35,  $P < .001$ ). However, the pooled analysis revealed that patients with AA did not have significantly lower serum calcium levels compared with controls (WMD  $-0.17$ , 95% CI  $-0.40$ ,  $0.06$ ,  $P = .143$ ). The authors concluded that screening for vitamin D deficiency and vitamin D supplementation may be beneficial in the treatment of patients with AA. In this context, a recent study in AA compared topical treatment with mometasone 0.1% cream alone to combined treatment with topical calcipotriol 0.005% ointment and mometasone 0.1% cream [159]. In that comparative analytical study with over 100 AA patients, group A patients ( $n = 50$ ) were advised to apply topical mometasone 0.1% cream along with topical calcipotriol 0.005% ointment each once daily, whereas patients of group B ( $n = 50$ ) were advised to apply only topical mometasone 0.1% cream in the same amount, once a day. Follow-up of all patients was done at 6, 12, and 24 weeks, and the outcome was assessed according to the Severity of Alopecia Tool (SALT) score at every visit. Both the groups were statistically comparable in terms of age ( $P = .694$ ) and sex ( $P = .683$ ) distribution. Baseline mean SALT score of group A and group B patients was 7.22 and 6.05,

respectively ( $P = .145$ ). At the end of 24 weeks, mean SALT score of group A and group B patients decreased by 4.24 and 3.39, respectively ( $P < .001$ ). The authors concluded that adding topical calcipotriol 0.005% ointment with topical mometasone 0.1% cream has higher efficacy than topical mometasone alone, in the treatment of alopecia areata.

Recently, a prospective study including 30 AA patients (mean serum 25(OH)D level  $7.65 \pm 4.50$  ng/mL; mean age  $28.9 \pm 9.96$  years; mean SALT score  $35.8 \pm 27.5$ , median disease duration 48 weeks) and 30 healthy controls (mean serum 25(OH)D level  $15.8 \pm 11.47$  ng/mL; mean age  $31.17 \pm 9.43$  years) was performed [160]. Twenty-nine (96.7%) patients were vitamin D deficient (25(OH)D  $< 20$  ng/mL), compared with 22 (73.3%) controls ( $P = .001$ ). Serum 25(OH)D levels inversely correlated with severity of the disease ( $r = -.256$ ,  $P = .17$ , and duration of disease but did not correlate with pattern of AA and VDR expression in tissue samples. VDR expression was reduced in all patients and was normal in controls. Inverse correlation of VDR was noted with presence of inflammation on histology ( $P = .02$ ). VDR upregulation posttreatment was seen only in 13% of patients and demonstrated no correlation with response to treatment. The authors concluded that vitD deficiency in AA correlates inversely with disease severity and duration. VDR expression is reduced in AA and inversely correlates with inflammation histologically but does not correlate with serum 25(OH)D levels, severity, pattern, or duration of illness [160].

## 6.5 Vitamin D and vitiligo

A systematic review and updated metaanalysis, which investigated the vitamin D status in vitiligo patients and which included 31 studies identified by searching PubMed and other databases, was published recently [161]. In this metaanalysis, the random effects model was used to obtain standardized mean differences and pooled correlation coefficients, metaregression and sub-group analyses were conducted to explore heterogeneity, and the presence of publication bias and the study robustness were tested using funnel plot and sensitivity analyses, respectively. Overall, this metaanalysis showed significantly decreased serum vitamin D levels (standardized mean difference =  $-1.03$ ;  $P < .0001$ ) in vitiligo patients compared with controls. Subgroup analysis revealed that vitiligo patients with indoor/urban work had a significantly lower vitamin D level when compared with their outdoor/rural counterparts (standardized mean differences =  $-0.45$ ;  $P = .03$ ). The sensitivity analysis indicated that no single study had a significant influence

on the overall outcome, suggesting the robustness of this metaanalysis. However, this study has some limitations including varied sample sizes and heterogeneous study populations from different countries. Coimbra and colleagues used their same strategy of giving very high doses of vitamin D, 35,000 IUs once daily for 6 months to patients with vitiligo [94]. The 16 patients were instructed to also be on zero calcium diet and to be well hydrated. 14 of the 16 patients with vitiligo had 25%–75% repigmentation. Serum concentrations of total calcium and ionized calcium did not change [94].

## 6.6 Vitamin D and skin aging

It has been shown convincingly by Andrzej Slominski, Georgeta Bocheva [162], and others that distinct cutaneous photoproducts, including active hydroxyderivatives of vitamin D<sub>3</sub> and lumisterol (L<sub>3</sub>) exert a variety of antiaging and photoprotective effects on the skin. These are at least in part achieved through immunomodulation and include beside antiinflammatory actions, regulation of keratinocytes proliferation, and differentiation programs to build and maintain the epidermal barrier necessary for skin homeostasis. In addition, these photoproducts have the capacity to induce antioxidative responses, inhibit DNA damage, and induce DNA repair mechanisms to attenuate premature skin aging and cancerogenesis. The mechanism of action that underlies these antiaging effects involve interaction with multiple nuclear receptors including VDR, AhR, LXR, reverse agonism on ROR $\alpha$  and  $-\gamma$ , and nongenomic actions through 1,25(OH)<sub>2</sub>D<sub>3</sub>-MARRS receptor and interaction with the nongenomic binding site of the VDR. Therefore, it has been concluded that active forms of vitamin D<sub>3</sub> including 1,25(OH)<sub>2</sub>D<sub>3</sub> and nonclassical (CYP11A1-initiated) D<sub>3</sub> derivatives as well as L<sub>3</sub> derivatives are promising agents for the prevention, attenuation, or treatment of premature skin aging. They could be administrated orally and/or topically. Other forms of parenteral application of vitamin D<sub>3</sub> precursor should be considered to avoid its predominant metabolism to 25(OH)D that is not recognized by CYP11A1 enzyme. The efficacy of topically applied vitamin D<sub>3</sub> and L<sub>3</sub> derivatives needs further clinical evaluation in future trials.

## 6.7 Sunscreens and vitamin D status

Global concern about vitamin D deficiency has fueled debates on photoprotection and the importance of solar exposure to meet vitamin D requirements [163]. An international panel of 13 experts in endocrinology, dermatology, photobiology, epidemiology, and biological anthropology reviewed the literature prior to a 1-day

meeting in June 2017, during which the evidence was discussed [163]. Methods of assessment and determining factors of vitamin D status and public health perspectives were examined, and consequences of sun exposure and the effects of photoprotection were assessed. A serum level of  $\geq 50$  nmol/L 25(OH)D is a target for all individuals. Broad-spectrum sunscreens that prevent erythema are unlikely to compromise vitamin D status in healthy populations. Vitamin D screening should be restricted to those at risk of hypovitaminosis, such as patients with photosensitivity disorders, who require rigorous photoprotection. Screening and supplementation are advised for this group. Sunscreen use for daily and recreational photoprotection does not compromise vitamin D synthesis, even when applied under optimal conditions. What's already known about this topic? Knowledge of the relationship between solar exposure behavior, sunscreen use, and vitamin D is important for public health, but there is confusion about optimal vitamin D status and the safest way to achieve this. Practical recommendations on the potential impact of daily and/or recreational sunscreens on vitamin D status are lacking for healthy people. What does this study add? Judicious use of daily broad-spectrum sunscreens with high ultraviolet (UV) A protection will not compromise vitamin D status in healthy people. However, photoprotection strategies for patients with photosensitivity disorders that include high sun-protection factor sunscreens with high UVA protection, along with protective clothing and shade-seeking behavior, are likely to compromise vitamin D status. Screening for vitamin D status and supplementation are recommended in patients with photosensitivity disorders.

## 6.8 Actinic keratoses, skin cancer

It has been reported in the literature that distinct polymorphisms of the VDR gene are associated with the presence of actinic keratoses and nonmelanoma and melanoma skin cancer [164,165], indicating that the vitamin D endocrine system (VDES) may be important for development of cutaneous malignancies. Moreover, some investigations indicate that topically applied vitamin D analogs may be effective in the treatment of actinic keratoses (cutaneous SCC in situ). Although it has been reported that actinic keratoses in renal transplant recipients do not improve with calcipotriol cream and all-trans retinoic acid (RA) cream as monotherapies or in combination during a 6-week treatment period [166]. However, other reports, including an investigator-blinded, half-side comparison trial, indicate that topically applied vitamin D analogs may be effective in the treatment of actinic keratoses [167]. In this

study [167], patients applied calcipotriol cream to one side and Ultrabase cream as placebo to the other side of the scalp and/or face for 12 weeks. The total number of actinic keratoses, diameters, and total scores of the target lesions were determined at each visit. Nine patients were included, eight of whom completed the treatment. There was a statistically significant difference between the total number of actinic keratoses at baseline and at week 12 on the calcipotriol applied side, whereas no difference was detected on placebo-applied side ( $P = .028$  vs.  $P = 1.00$ ). The mean total score of the target lesions reduced significantly at week 12 on calcipotriol side; in contrast, no significant reduction was found on placebo side ( $P = .017$  vs.  $P = .056$ ). In conclusion, although the study was suggestive, the clinical efficacy of vitamin D analogs in the topical treatment of actinic keratoses remains to be elucidated in future investigations.

In vitro studies have demonstrated strong antiproliferative and prodifferentiating effects of vitamin D analogs in many VDR-expressing tumor cell lines, including malignant melanoma, SCC, breast and lung cancer, and leukemic cells [168–172]. In vivo studies supported these results and showed that active-vitamin D analogs block proliferation and tumor progression of epithelial tumors in rats [172]. Inhibition of tumor growth of human malignant melanoma and other cancer xenografts was also demonstrated in immune-suppressed mice but only with high doses of calcitriol [172]. Little is known regarding the effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> on the formation of metastases in patients with malignant melanoma or SCC of the skin.

## 6.9 Acne

The therapeutic efficacy of vitamin D in acne has been investigated in the middle of the past century [173–176] with limited success. However, more recent laboratory investigations and animal studies indicate that vitamin D compounds may be effective in acne treatment [177]. In the rhino mouse model, a comedolytic effect of topically applied active vitamin D<sub>3</sub> analog maxacalcitol on pseudocomedones was demonstrated [177]. The rhino (*hr<sup>rh</sup>/hr<sup>rh</sup>*) phenotype is because of an autosomal recessive mutation in the hairless (*hr*) gene [177]. In the rhino mouse, utriculi are derived from the infundibular zone of the initial follicular units and are histologically similar to comedones [177]. The rhino mice were treated topically with tretinoin and maxacalcitol once daily for 2 and 4 weeks, respectively. The dermal side of the epidermal sheet was observed to determine the size of the utricle. Hematoxylin and eosin-stained vertical sections were used to measure utricle diameter and density and to evaluate histological changes. Maxacalcitol

(25 µg/g) and tretinoin (0.1%) significantly decreased the size and the diameter of the utricle after 1 week of treatment. Histopathologically, maxacalcitol and tretinoin markedly induced epidermal hyperplasia accompanied by a minor accumulation of inflammatory cells in the dermis, with and without hypercornification, respectively. These results indicate that maxacalcitol has an effect on comedolysis and that its mechanism of action may be different from that of retinoids. The clinical relevance of these observations remains to be elucidated in future investigations.

## 6.10 Cutaneous wound healing and skin health

Because 1,25(OH)<sub>2</sub>D<sub>3</sub> and its analogs were such potent inhibitors of keratinocyte and fibroblast proliferation, there was concern that its topical application could result in skin atrophy and poor wound healing that is seen with topical steroids. However, Tian et al. [178] observed that the topical application of 1,25(OH)<sub>2</sub>D<sub>3</sub> markedly enhanced wound healing compared with the topical application of a control vehicle or vitamin D<sub>3</sub>. As little as 5–50 ng of topically administered 1,25(OH)<sub>2</sub>D<sub>3</sub> to the wound in rats increased wound healing by 75% on the first day compared with the control group. This accelerated wound healing continued until it was healed.

When the skin is wounded, it triggers an acute inflammatory response with the innate immune system helping to protect against invasive organisms. 1,25(OH)<sub>2</sub>D<sub>3</sub> upregulates the antimicrobial peptide hCAP18/LL-37(cathelicidin) [179] to help reduce infection. The inflow of inflammatory cells into the wounded area results in the release of cytokines and growth factors to initiate proliferation and migration of dermal and epidermal cells. Mice lacking the VDR when placed on a low-calcium diet have a delayed wound healing. This was associated with reduced β-catenin transcriptional activity and proliferation in the cells at the leading edge of wound closure. Thus, it was concluded that vitamin D and calcium signaling are necessary components of the epidermal response to wounding by regulating stem cell activation through increased β-catenin transcriptional activity [180].

Thus 1,25(OH)<sub>2</sub>D<sub>3</sub> is a potent modulator of skin health. Under conditions of hyperproliferation, such as psoriasis and actinic keratoses, this hormone can induce a variety of biologic processes (cytokines and growth inhibitory factors) to help restore normal proliferation and improve skin health. However, if the skin becomes atrophic because of topical steroid use or is wounded, 1,25(OH)<sub>2</sub>D<sub>3</sub> is able to induce other biologic processes (cytokines and growth factors) to restore normal skin growth and enhance wound healing.

## 6.11 Other skin diseases

A number of case reports demonstrate positive effects of topical treatment with vitamin D analogs in a variety of skin diseases such as transient acantholytic dermatosis (Grover's disease), inflammatory linear verrucous epidermal naevus, disseminated superficial actinic porokeratosis, pityriasis rubra pilaris, epidermolytic palmoplantar keratoderma of Vörner, confluent and reticulated papillomatosis (Gougerot–Carteaud syndrome), and Sjögren–Larsson syndrome [181,182].

## 7. Evaluation of new vitamin D analogs, with less calcemic activity, which can be used for the treatment of hyperproliferative skin disorders

The use of vitamin D analogs in dermatology and other medical fields was shown to be limited because serious side effects, mainly on calcium metabolism, may occur at supraphysiological doses needed to reach clinical improvement [183–186]. The evaluation of new vitamin D compounds with strong immunosuppressive, antiproliferative, and differentiating effects, but only marginal effects on calcium metabolism introduce new important therapies for the treatment of various skin diseases. The goal to create new vitamin D analogs with selective biological activity and no undesirable side effects has still not been reached, but recent findings introduce new and promising concepts. Chapters 45 and 46 of this book discuss the development of 1,25(OH)<sub>2</sub>D<sub>3</sub> analogs.

Calcipotriol (MC 903) with similar VDR binding properties compared with 1,25(OH)<sub>2</sub>D<sub>3</sub>, but low affinity for the vitamin D-binding protein (DBP), is well known to be effective and safe in the topical treatment of psoriasis [86]. In vivo studies in rats showed that effects of calcipotriol on calcium metabolism are 100–200 times lower as compared with 1,25(OH)<sub>2</sub>D<sub>3</sub>, whereas in vitro effects on proliferation and differentiation on human keratinocytes are comparable. These differential effects are probably caused by the different pharmacokinetic profiles of calcipotriol and 1,25(OH)<sub>2</sub>D<sub>3</sub> due in part to different affinities for DBP. Serum half-life in rats of these vitamin D analogs was shown to be 4 minutes after treatment with calcipotriol in contrast to 15 minutes after treatment with 1,25(OH)<sub>2</sub>D<sub>3</sub> [reviewed in 172]. However, most of the calcium metabolic studies comparing 1,25(OH)<sub>2</sub>D<sub>3</sub> and calcipotriol were done in vivo, whereas most studies analyzing proliferation or differentiation were done in vitro. The rapid degradation of calcipotriol after systemic administration has limited its oral use but made it an ideal drug for topical use.

A different approach to create new vitamin D analogs that are effective in the topical treatment of

hyperproliferative or inflammatory skin diseases is the goal to create new synthetic compounds that are metabolized in the skin and therefore exert only limited systemic side effects. Vitamin D analogs, obtained by a combination of the 20-methyl modification with biologically interesting artificial side chain subunits [184] or 2 $\beta$ -substituted 1,25(OH) $_2$ D $_3$  [185], are promising candidates for this approach.

Another interesting approach to enhance the local concentration of 1,25(OH) $_2$ D $_3$  in the skin without obtaining systemic side effects is an attempt to specifically inhibit the activity of vitamin D–metabolizing enzymes, i.e., various hydroxylases (catabolic D $_3$ -OHases for 1,25(OH) $_2$ D $_3$ ) that are present in the skin and that are responsible for the catabolism of 1,25(OH) $_2$ D $_3$  [186]. It is known that various pharmacologic active compounds, including not only other steroidal hormones but also cytochrome P450 inhibitors as ketoconazole, inhibit the activity of vitamin D hydroxylases in the skin [187]. It may be possible to locally enhance the concentration of endogenous calcitriol in the skin by the topical application of these compounds without obtaining systemic side effects. It can be speculated that the therapeutic effects of various antimycotic compounds including ketoconazole in the treatment of seborrheic dermatitis may at least in part be because of this mechanism. It is now known that VDR requires nuclear accessory proteins for efficient binding to vitamin D response elements in promoter regions of target genes, thereby inducing VDR-mediated transactivation [186]. As a consequence, different vitamin D analogs may have (depending on their chemical structure) different affinities for the various homo- or heterodimers of VDR and nuclear cofactors including RXR $\alpha$  [188,189]. The synthesis of new vitamin D analogs that activate different vitamin D signaling pathways may lead to the introduction of new therapeutics for the topical or oral treatment of various skin diseases. These new drugs may induce strong effects on target cell proliferation and differentiation in the skin or the immune system but only marginal effects on calcium metabolism. Another approach to enhance the therapeutic effects of orally or topically administered 1,25(OH) $_2$ D $_3$  may be the combination with synergistic acting drugs. The discovery of different vitamin D signaling pathways that are determined and regulated by cofactors of VDR including RXR $\alpha$  and their corresponding ligands suggests that 9-cis RA or all-trans RA may act synergistically with vitamin D analogs to induce VDR-mediated transactivation and regulate the transcriptional activity of distinct gene networks [188,189]. Only a little is known about the effects of the combined application of vitamin D and vitamin A analogs under physiological or pathophysiological conditions *in vivo* [188,189]. This combination may

selectively enhance or block different biological effects of vitamin D analogs that are mediated by different vitamin D signaling pathways.

## 8. Conclusion

It can be speculated that innovative vitamin D analogs will introduce novel alternatives for the treatment of various skin disorders. If the final goal to create strong antiproliferative and antiinflammatory vitamin D analogs with only minor calcemic activity is reached, these new agents would herald a new era in dermatologic therapy, which possibly can be compared with the introduction of synthetic corticosteroids or retinoids. These new drugs may activate selective vitamin D signaling pathways, but may exert only negligible calcemic activity, and may also be effective in the systemic treatment of various skin malignancies, including lymphomas, cutaneous squamous cell carcinomas (SCCs), or basal cell carcinomas (BCCs). Unfortunately, although thousands of analogs of 1,25(OH) $_2$ D $_3$  have been produced, most have not satisfied all the desired criteria, i.e., having prolonged potent therapeutic activity while at the same time having no toxic consequences on calcium and bone metabolism. One promising avenue of investigation is the resurrection of the use of very high doses of vitamin D. Although the pioneering studies in the 1930s–1950s using high-dose vitamin D to treat psoriasis demonstrated efficacy, it also resulted in significant toxicity mainly because of lack of understanding, at that time, how vitamin D functioned on calcium metabolism and that it required further metabolism. To mitigate the toxic calcium–related side effects of high-dose vitamin D, Finamor [94] developed a protocol using high-dose vitamin D $_3$  with strict guidelines to eliminate all calcium from the diet to treat a variety of autoimmune disorders, including psoriasis and vitiligo. Recently, it was observed that very high doses of vitamin D daily for 10 days were effective in treating congenital ichthyosis. Therefore, there continues to be promised for the use of 1,25(OH) $_2$ D $_3$  and its analogs as well as vitamin D $_3$  itself in high doses for the treatment of a variety of an inherited and acquired skin disorders.

## 9. Summary points

- Provides the reader with a historical perspective on the use of vitamin D $_3$  and active vitamin D $_3$  and its analogs in dermatology.
- Provides the reader with an understanding of how 1,25-dihydroxyvitamin D $_3$  and its active analogs

affect the immune system and keratinocyte proliferation and differentiation.

- Provides the reader with information on the clinical utility of 1,25-dihydroxyvitamin D<sub>3</sub> and its analogs for the treatment of psoriasis.
- Provides the reader with up-to-date information on the clinical use of 1,25-dihydroxyvitamin D<sub>3</sub> for the treatment of ichthyosis.
- Provides the reader with an understanding of how to safely use pharmacologic doses of vitamin D<sub>3</sub> to treat psoriasis, vitiligo, and ichthyosis.

# Vitamin D, acute respiratory infection, and Asthma/COPD

Carlos A. Camargo, Jr.

Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, MA, United States

## OBJECTIVES

- The chapter will describe how vitamin D plays an important role in regulating innate and adaptive immune responses that are central to normal respiratory function.
- The chapter will outline how vitamin D deficiency has been linked to common respiratory disorders including asthma and chronic obstructive pulmonary disease (COPD).
- Observational and interventional studies of vitamin D and acute respiratory infection (ARI), asthma, and COPD will be detailed.

## 1. Introduction

For most of the 20th century, medical research on sunlight and vitamin D focused on calcium-phosphate homeostasis and bone health, particularly the prevention and treatment of rickets. Nevertheless, one of the first Nobel Prizes in Physiology and Medicine was awarded in 1903 to Dr. Niels Ryberg Finsen for his discovery of the beneficial effects of sunlight on cutaneous tuberculosis (TB) [1]. This novel *infectious disease* finding led to important changes in the clinical management of pulmonary TB worldwide, including the development of mountain clinics to provide afflicted patients with better access to sunlight and fresh air [2]. Although the link between sunlight exposure and vitamin D synthesis, and between vitamin D deficiency and TB, was widely

appreciated during the first half of the 20th century, the role of sunlight and vitamin D on respiratory infection was largely neglected during the latter half of the 20th century.

Over the past 25 years, however, researchers around the world have again taken interest in the antimicrobial potential of sunlight and vitamin D [3,4]. For example, while initial studies in the 1990s demonstrated an association between nutritional rickets and ARI among children in developing nations [5,6], many studies since have found an association between vitamin D and ARI risk in otherwise well-nourished individuals, of all ages, in many developed nations [7,8]. Research has progressed rapidly, from small cross-sectional and case-control studies to large prospective cohort studies and randomized controlled trials (RCTs).

With growing evidence that the vitamin D hormone has complex immunologic effects, it was not surprising that some investigators raised health concerns about this supplementation. Most notably, Wjst and Dold proposed in 1999 that vitamin D supplementation might be a *cause* of the global increases in asthma and other allergic disorders [9]. Genetic association studies were undertaken to address this putative harm by examining if specific polymorphisms of the vitamin D receptor (VDR) gene were associated with an increased risk of asthma. Although these asthma genetics studies showed some statistically significant associations, the results conflicted across individual datasets and studies [10–13]; the relationship between VDR polymorphisms and asthma remained unclear.

In this context, Camargo et al. proposed the *opposite* hypothesis of Wjst et al. at the 2006 Annual Meeting of the American Academy of Allergy, Asthma, and

Immunology [14]—i.e., that widespread vitamin D *deficiency* (not excess) might explain recent increases in childhood wheezing and asthma. The investigators presented original evidence for this hypothesis from a Boston birth cohort study involving almost 1200 mother-child pairs. In brief, the investigators found that maternal intake of vitamin D during pregnancy had a striking inverse association with the risk of recurrent wheezing in offspring. Because most wheezing illness of childhood represents uncomplicated ARI, rather than incident asthma [15], the authors cautioned that further research would need to distinguish between simple ARIs (with consequent wheezing) versus a true diagnosis of childhood asthma.

Over the past 15 years, the relation of low vitamin D status with ARIs and asthma has become a focus of research teams worldwide. Indeed, major professional society meetings today, in both the pulmonary and allergy/immunology communities, often include lectures or entire symposia on vitamin D. This chapter examines the relation of vitamin D to childhood wheezing and asthma, along with emerging evidence on the role of vitamin D among adults with COPD. To decrease overlap with other parts of [Section 11](#) of this book on immune function and inflammation (notably Chapter 96), this chapter will touch only briefly on the immunologic mechanisms that likely mediate these clinical and epidemiological observations. Likewise, this chapter will touch only briefly on the emerging evidence on the relation of vitamin D with atopy and allergic diseases (such as atopic dermatitis, food allergy, and allergic rhinitis), given their mechanistic links with childhood asthma [16].

## 2. Common respiratory disorders

To better understand the effect of vitamin D on common respiratory disorders, it is important to discuss, at least briefly, some of the methodological challenges of research in this area, especially the complex interrelations between these disorders. This section provides key background information on respiratory infections, childhood wheezing, asthma, and COPD. The text then returns to the role of vitamin D in each of these disorders.

### 2.1 Respiratory infections

Respiratory infections are a diverse and complex group of infections that have always been a major cause of morbidity and mortality [17,18], as demonstrated by the COVID-19 pandemic. Although these infections are frequently categorized anatomically into *upper* versus *lower* respiratory tract infections, respiratory infections

may (and often do) involve multiple anatomic locations. Another method of categorization is according to a pathogen, with infections commonly divided into *viral* versus *bacterial*. For some infections with respiratory involvement, researchers and the general public commonly identify them by the *specific pathogen* alone, as is true for influenza and TB. There also are basic issues of disease chronicity (i.e., *acute* vs. *chronic* infection). As a result of these and other considerations, clinical and epidemiologic research on the relationship between vitamin D and “respiratory infections” has proven quite challenging.

Bronchiolitis provides an excellent example of the complexity of research on ARIs. Although bronchiolitis is the leading cause of hospitalization in infants and has high annual costs [19], there is no global consensus regarding its definition. Because bronchiolitis remains a somewhat vague clinical diagnosis, it should not surprise readers that clinicians differ on who exactly has the illness [20]. In 2006, an American Academy of Pediatrics position paper described the typical child with bronchiolitis as being age <2 years and having “rhinitis, tachypnea, wheezing, cough, crackles, use of accessory muscles, and/or nasal flaring” [21]; the definition did not materially change in the updated 2104 guidelines [22]. In other countries, however, many investigators believe that bronchiolitis *only* should be diagnosed in infants (defined as age <1 year), or that the presence of specific exam findings (e.g., crackles) should be mandatory.

Although the microbiology of bronchiolitis might help with classification, there is a spectrum of clinical disease that is not understood. For example, while almost all children are infected by age 2 years with respiratory syncytial virus (RSV) [23,24], the leading cause of severe bronchiolitis [25–27], most children infected with RSV do not present to an acute care setting with clinical bronchiolitis [23,28]. Indeed, <10% of US children infected with RSV will present to the emergency department with bronchiolitis, and only 2%–3% of all children are hospitalized [27,29,30]. To further complicate matters, not only is there a growing list of other viruses linked to bronchiolitis ([Table 105.1](#)), including rhinovirus [27,31,32], but it is clear that multiple pathogen infections (co-infections) are common [33,34]. Even without considering the different short-term and long-term clinical implications of these different forms of bronchiolitis [35], one can quickly understand the complexity of classifying, let alone studying, this common ARI of childhood.

In summary, the heterogeneity of “respiratory infection” makes it challenging to link an individual factor like vitamin D to the risk of developing this composite outcome. To be more specific, vitamin D might have an important association with some, but not all, types

**TABLE 105.1** Frequency of common viruses linked to bronchiolitis, according to healthcare setting.

	Outpatient <sup>a</sup>	Emergency <sup>b</sup>	Inpatient <sup>c</sup>
Respiratory syncytial virus	11%–27%	64%	73%
Rhinovirus	46%–49%	16%	26%
Parainfluenza	5%–13%	n/a	3%
Influenza	1%–5%	4%	1%
Metapneumovirus	2%	7%	7%
Combination infections	10%–17%	14%	30%

<sup>a</sup>Based on upper and lower acute respiratory infections during infants' first winter [195] and first year [196].

<sup>b</sup>Based on children presenting to 14 U.S. emergency departments [197].

<sup>c</sup>Based on children admitted to 16 U.S. hospitals [33].

Abbreviation: n/a denotes not available.

of respiratory infections, as defined by either specific anatomical areas or by specific pathogenic organisms. Vitamin D also might influence disease severity. For example, while all children may at some point be infected with RSV, perhaps only those with low serum 25-hydroxyvitamin D (25(OH)D) levels—or other predisposing factors—develop severe enough RSV infections to require hospitalization or intensive care. If these different hypotheses are true, the common practice of collapsing diverse infections into one composite “respiratory infection” outcome would likely obscure real associations—i.e., one would conclude that there was no association when, in fact, there was. Studies on the relation of sunlight and vitamin D status to ARI (and associated disorders) need to be interpreted with this important caveat in mind.

## 2.2 Childhood wheezing

The heterogeneity of respiratory infections is similar to that of childhood wheezing. After all, many different conditions can cause “wheezing,” which is just a musical sound caused by the passage of air through narrowed respiratory tract airways [36]. Across the lifespan, this airway narrowing probably is caused most often by ARIs. For individuals with asthma or COPD, however, the airway narrowing and associated wheezing could result from a complex mixture of either baseline or exacerbated inflammation/edema and bronchoconstriction, often but not always with concurrent infection. In all ages, wheezing also can be caused by other, less common conditions. A classic cause of childhood wheezing unrelated to asthma is an airway foreign body [37]. Among adults, decompensated heart failure—with so-called cardiac wheezing—is common asthma/COPD mimic in the acute care setting [38].

Population-based cohort studies have provided important information about the natural history of childhood wheezing. For example, the landmark studies of Martinez et al. clearly demonstrate that many children who wheeze in early childhood have only transient episodes (during ARIs) and do *not* go on to develop asthma [15,39]. Accordingly, asthma researchers try, with varying levels of success, to divide wheezing children into different clinical groups. In one system, children are grouped into (1) transient early wheezing, (2) late-onset wheezing, or (3) persistent wheezing (i.e., when the wheezing was present during both early and late periods of early childhood). In another system, children are grouped into: (1) transient early wheezers, (2) nonatopic wheezers, or (3) IgE-associated wheeze/asthma (Fig. 105.1). Although these groupings help to divide children according to their likelihood of developing asthma by age 6 years, many children—in all groups—do *not* develop asthma. Studies have repeatedly affirmed the clinical adage that “All that wheezes is not asthma.” To further emphasize the difference between childhood wheezing and asthma, many young children with asthma present with recurrent nocturnal cough and lack any evidence of wheezing [40]. For all of these reasons, one should be very cautious about generalizing from findings about childhood wheezing to actual asthma. This cautionary note applies even to *recurrent* wheezing, which may simply represent recurrent ARIs in a nonasthmatic child. Since young children are estimated to experience 6 to 10 ARIs per year [41], clinicians (and researchers) might anticipate that many attentive parents may report recurrent “wheezing” in their children and that this could be mistakenly called asthma.

## 2.3 Asthma

Asthma is a common medical condition that is associated with high morbidity and health care utilization [42]. Diagnosis and management guidelines are available from both the U.S. National Institutes of Health [43] and an international group called the “Global Initiative for Asthma” [44]. Although defining asthma challenged clinicians for centuries, there now is general acceptance of the 1987 definition from the American Thoracic Society (ATS) [45]—i.e., asthma is a chronic lung disease characterized by: (1) airway narrowing that is reversible (though not always completely), either spontaneously or with treatment; (2) airway inflammation; and (3) bronchial hyper-responsiveness to a variety of stimuli.

Although the ATS asthma definition is clear, it has proven very difficult to apply in epidemiologic studies, where subjects may be dispersed over large

**FIGURE 105.1** Hypothetical prevalence of three different wheezing phenotypes in childhood. For each age interval, the overall wheezing prevalence is the sum of the areas under each curve. The dashed lines emphasize the possibility of different curve shapes due to many factors, including overlap between the three groups. Adapted from Ref. [194].

geographic areas and where spirometry and hyper-responsiveness testing usually are not feasible. As a result, asthma epidemiologists have relied on much simpler definitions of asthma, such as an affirmative response to the question: “Do you have doctor-diagnosed asthma?” Although the potential limitations of this epidemiologic approach are self-evident, this approach actually performs with adequate accuracy [46] to allow epidemiologists to perform asthma surveillance and to examine potential risk factors for the disease. Similar questions have, in fact, contributed to widespread concern about the dramatic rise in “asthma” prevalence for several decades [47].

While viral ARIs are common triggers of asthma exacerbations [48,49], and these exacerbations occur across the lifespan, the vast majority of asthma begins in early childhood. Estimates vary but approximately 80%–90% of asthma begins before age 6 years, with 70% of asthmatic children having asthma symptoms before age 3 years [50,51]. The etiology of asthma has proven elusive, but these clinical observations indicate that the major risk factors must be present in early life—either in utero or at least in the first months/year of childhood [52]. Childhood atopy is one of the strongest risk factors for asthma [16,53], yet substantial numbers of asthmatic individuals are non-atopic [54]. Indeed, a growing number of asthma researchers acknowledge that the term “asthma” is likely a *syndrome* composed of heterogeneous diseases [55], with significant overlap with COPD [56]; the etiologic factors and treatments of one type of asthma may differ from those of another.

## 2.4 Chronic obstructive pulmonary disease

COPD is another common medical condition that is associated with high morbidity and mortality [57]. The most widely accepted definition for COPD comes from the “Global Initiative for Chronic Obstructive Lung Disease” (GOLD): COPD is “a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases and influenced by host factors including abnormal lung development. Significant comorbidities may have an impact on morbidity and mortality.” [57].

Even more so than for asthma, there have been significant disagreements about the definition of COPD over the past 50 years. Classical descriptions of COPD emphasized two major types: “chronic bronchitis” and “emphysema.” Although these COPD types continue to be taught to healthcare professionals, there now is universal recognition of their considerable overlap. Uncertainty regarding COPD diagnosis has been compounded by the fact that chronic bronchitis was, for many years, a *clinical* diagnosis (e.g., requiring that the patient have a daily cough productive of sputum for at least 3 months over at least two consecutive years) while emphysema was an *anatomic* diagnosis requiring actual parenchymal destruction. By contrast, the GOLD guidelines acknowledge that the chronic airflow limitation characteristic of COPD is caused by a mixture of small airway disease (obstructive bronchiolitis) and

parenchymal destruction (emphysema), with the relative contributions of these pathological changes varying from person to person [57]. The evolving definition of COPD requires careful attention to case definition when integrating study results across recent decades. As with asthma, the etiologic factors and treatments of one type of COPD may differ from those of another.

Unlike asthma, which usually starts in early childhood but can begin in adulthood (e.g., occupational asthma), COPD manifests much later in life, typically after decades of tobacco smoke inhalation [57]. Moreover, while both asthma and COPD are “obstructive lung diseases” characterized by virus-induced exacerbations, acute exacerbations of COPD (AECOPD) are more heterogeneous than those of asthma; this has several explanations but one reason is that elderly smokers are likely to suffer from other health problems (e.g., cardiovascular disease) and these can contribute to the presentation and clinical course of AECOPD. Thus, while it is tempting for researchers to generalize vitamin D-related findings from asthma to COPD, or vice versa, this should be done cautiously given important differences between these separate, but overlapping, obstructive airway disorders.

### 3. Vitamin D and lung development

Although the physiologic role of vitamin D in the developing fetus, neonate, and infant is discussed in Chapter 33, lung development is so critical to the development of asthma and COPD that it merits special comment here. Briefly, human lung development begins around 4 weeks gestation and the bronchi and major branches develop in the first few months of fetal growth. The development of alveolar units probably continues after birth, but it is generally believed that branching of the airways does not. Although there are limited data about the role of vitamin D in human lung development, rat models may provide insights into some of the critical steps in lung development across species. For example, pulmonary surfactant is a mostly phospholipid complex present in the alveolus to reduce surface tension and regulate innate immune function, and it is critical to lung development [58]. In a 1990 publication, Marin et al. demonstrated, in explanted fetal rat lung tissue, that 1,25-dihydroxyvitamin D ( $1,25(\text{OH})_2\text{D}$ ) stimulates the synthesis of pulmonary surfactant phospholipids and the release of surfactant from alveolar type II (AT II) cells [59]. A 1996 publication by the same group showed that fetal rat lung fibroblasts in late pregnancy produce  $1,25(\text{OH})_2\text{D}$ , which binds to numerous VDRs on AT II cells and thereby stimulates the production of pulmonary surfactant [60]. These findings led the authors to propose the existence of a vitamin

D paracrine system that regulates the maturation of the rat lung.

While these rat lung data are intriguing, their relevance to humans is uncertain. For example, a 2005 study of human fetal lung tissue demonstrated that  $1,25(\text{OH})_2\text{D}$  does *not* induce the expression of surfactant proteins in a coordinated manner [61]. Moreover, lung development requires many other complex steps, including thinning the alveolar septal wall to allow effective gas exchange [62]. This thinning is thought to occur via apoptosis of lung fibroblasts [63]. Sukurai et al. explored this issue in fetal rat lungs and found that  $1,25(\text{OH})_2\text{D}$ , acting via local effects, promotes alveolar epithelial-mesenchymal interactions and inhibits lipofibroblast atoptosis [64]. Moreover, the investigators found that rat pups administered  $1,25(\text{OH})_2\text{D}$  postnatally showed increased expressions of key lipofibroblast and AT II cell differentiation markers, decreased spontaneous alveolar lipofibroblast and ATII cell apoptosis, increased alveolar count, and increased septal thickness. Work by Nadeau et al. also suggests complex effects of  $1,25(\text{OH})_2\text{D}$  on rat lung development during the postnatal period [65]. These investigators demonstrated a complex integration of the effects of glucocorticoids, retinoic acid, and  $1,25(\text{OH})_2\text{D}$  on gene expression in the postnatal lung, specifically *Lgl 1*; the authors concluded that all three hormones probably contribute to the timely advance of alveolarization without attendant inflammation.

In 2011, Zosky et al. reported on their mouse model of vitamin D deficiency, in which they had studied offspring from both vitamin D deficient and vitamin D replete colonies of mice at 2 weeks of age [66]. The investigators found that vitamin D deficiency caused lung function deficits that were primarily explained by differences in lung volume. In 2014, Yurt et al. used an in vivo rat model to determine the pulmonary effects of perinatal vitamin D deficiency and reported compelling evidence for the potential role of vitamin D supplementation in asthma prevention [67]. Briefly, the investigators found that perinatal vitamin D deficiency altered airway contractility and that this effect was not seen in the offspring of maternal rats given vitamin D supplementation. Most recently, in 2021, Sakurai et al. reported in their established rat model that perinatal vitamin D deficiency alters lung mesenchymal cell proliferation and differentiation [68]. These observations lend support to vitamin D deficiency as a contributing factor to the increased respiratory morbidity seen in children born to mothers with vitamin D deficiency.

In sum, studies over the past 30 years support the presence of a vitamin D paracrine system in both the fetal and postnatal rat lung and the potential for asthma/COPD prevention. While much remains to be learned about the connection of vitamin D to human

lung development, it seems likely that vitamin D is playing some role in this complex process. Very low or very high levels of vitamin D—either locally or systemically—might have lasting adverse effects on lung development and function. Although speculative, such effects would provide a mechanism for how gestational and even postnatal vitamin D status could influence respiratory health.

## 4. Vitamin D and acute respiratory infection

As noted earlier, the first clear link between vitamin D and infectious disease goes back more than a century to the TB research of Dr. Finsen, who discovered that concentrated light radiation was an effective treatment for lupus vulgaris (cutaneous TB) [1]. Although he was not aware of the mechanism for this therapeutic benefit, scientists today would attribute his treatment successes, at least in part, to UVB-induced increases in vitamin D. For the past 20 years, investigators around the world have focused on the link between vitamin D status and chronic infection with TB. Observational studies have provided promising evidence for an inverse association between vitamin D and TB [69], but more recent RCTs have not shown benefits [70,71]. Global investigators have also investigated, more generally, the link between sunlight, vitamin D, and a variety of infectious diseases [4]. The effect of vitamin D on ARI may be distinct from TB or infections in general. Either way, it is central to understanding the relation of vitamin D with asthma and COPD. The underlying immunologic mechanisms are discussed in more detail in Chapters 94–99.

### 4.1 Observational studies on ARI, including childhood wheezing

Over the past 25 years, many researchers have repeatedly observed that vitamin D appears to have antimicrobial activity, not only against TB but against a broad range of more acute respiratory pathogens. Several early studies showed that nutritional rickets was associated with a higher risk of ARIs [5,6,72] and worse treatment outcomes [73]. However, the relationship between low but nonrachitic 25(OH)D levels and ARI was less clear. While many countries now have a low population prevalence of rickets, they continue to have high rates of vitamin D deficiency [74,75] so the question remains one of major public health importance.

In a 2013 systematic review, Jolliffe et al. identified 25 eligible observational studies (4 cross-sectional, 8 case-control, 13 cohort) on vitamin D and ARI [8]. The authors found that these studies predominantly reported statistically significant associations between low vitamin

D status and increased risk of both upper and lower ARI. The studies involved large numbers of participants of all ages in diverse geographical settings. Moreover, they had a wide distribution of serum 25(OH)D concentrations. Cohort studies were plentiful and thereby confirmed that vitamin D deficiency truly preceded the onset of ARI; reverse causality was highly unlikely. Over the past decade, many more observational studies have supported these conclusions. In a recent meta-analysis by Pham et al. [76], the investigators reported an inverse, nonlinear association between 25(OH)D level and the risk of ARI. They observed that the sharpest increase in ARI risk occurred at 25(OH)D levels less than 15 mg/mL (37.5 nmol/L).

Because most *childhood wheezing* is caused by ARI and is not indicative of actual asthma [15,39], it seems most appropriate to review the observational studies on vitamin D and childhood wheezing in this ARI section. (By contrast, because most RCTs of maternal/infant vitamin D supplementation are clearly aimed at the primary prevention of childhood asthma, they are reviewed in the “Vitamin D and Asthma” section that follows). In 2005, Camargo et al. started to investigate the relation between vitamin D status and childhood wheezing in a Massachusetts birth cohort called Project Viva [77]. The investigators found that lower maternal intake of vitamin D during pregnancy was associated with significantly increased offspring risk of recurrent wheezing. In these 1194 mother-child pairs, the mean (SD) total vitamin D intake during pregnancy was 548 [78] IU/day. By age 3 years, 186 children (16%) had recurrent wheeze. Compared with mothers in the lowest quartile of daily intake (median: 356 IU), those in the highest quartile (724 IU) had substantially lower odds of having a child with recurrent wheeze (OR 0.39; 95% CI 0.25–0.62; P for trend <0.001). An increase in vitamin D intake was associated with lower odds, regardless of whether vitamin D was from diet or from supplements. Adjustment for 12 potential confounders, including maternal intake of other dietary factors, did not change the results. Although the “respiratory infection” outcome was crude, it also showed an inverse association and favored an infectious disease explanation for the study results [77].

The Boston findings on maternal intake of vitamin D and childhood wheezing were replicated in a Scottish birth cohort by Devereux et al. [79]. In these 1212 mother-child pairs, the median (interquartile range) vitamin D intake during pregnancy was 128 [80–142] IU/d, which was significantly lower than the intake of the Boston mothers [77]. Nevertheless, compared to mothers in the lowest quintile of daily intake (median: 77 IU), those in the highest quintile (275 IU) had a lower risk for ever wheeze (OR 0.48; 95%CI 0.25–0.91), wheeze in the previous year (OR 0.35; 95%CI 0.15–0.83), and

persistent wheeze (OR 0.33; 95%CI 0.11–0.98) in the 5-year-old children. In contrast to these impressive vitamin D-wheeze findings, there was no association between maternal vitamin D intake during pregnancy with doctor-diagnosed asthma at age 5 years ( $P = .98$ ).

Since the 2007 publication of these two studies [77,79], many cohorts from around the world have examined these same questions, using diverse measures of vitamin D status and definitions of wheezing (and early childhood “asthma”). A 2011 systematic review by Nurmatov et al. identified a total of eight eligible observational studies on maternal vitamin D status during pregnancy and offspring risk of childhood wheezing/asthma [143], including the Boston and Scotland cohorts presented above. Pooled analysis of the four large cohort studies showed that higher maternal intake of vitamin D during pregnancy was associated with reduced odds of wheezing, either recurrent or wheeze in the previous year (OR 0.56; 95%CI, 0.42–0.73). Pooled analysis from the two available cohort studies [79,144] showed that maternal vitamin D intake was not associated with asthma at age 5 years ( $P = .42$ ). These important findings (inverse association with wheezing but no association with actual asthma) were affirmed in a 2015 systematic review by Beckhaus et al. [145].

In the New Zealand Asthma and Allergy Cohort Study, Camargo et al. first examined the association between low cord blood levels of 25(OH)D and subsequent risk of ARIs and childhood wheezing [146]. The availability of 25(OH)D levels provided a distinct advantage to prior studies since it better-assessed vitamin D status than self-reports of oral intake alone. In this birth cohort

of 922 children with cord blood specimens available for assay, 20% of children had cord blood 25(OH)D level  $<10$  ng/mL, and 73% (cumulative) had a 25(OH)D level  $<30$  ng/mL. Cord blood 25(OH)D level was inversely associated with odds of ARI by age 3 months: children with 25(OH)D levels  $<10$  ng/mL were at a twofold higher odds than those with levels  $\geq 30$  ng/mL (OR 2.04; 95%CI 1.13–3.67). These prospective findings were independent of season and 14 other potential confounders and provided strong evidence for a protective effect of vitamin D on the risk of ARI. Indeed, cord blood 25(OH)D level also had an inverse association with risk of wheezing illness at ages 15 months, 3 years, and 5 years (all  $P < .05$ ; see Fig. 105.2). By contrast, cord blood 25(OH)D level had no association with doctor-diagnosed asthma at age 5 years ( $P = .37$ ).

Over the past decade, several groups from around the world have confirmed the inverse association between maternal and early childhood vitamin D status and risk of ARI/wheeze. For example, Saraf et al. performed a nested case-control study in large prebirth cohort in New Zealand [147] and found that birth 25(OH)D levels  $<20$  ng/mL were associated with significantly elevated odds of ARI hospitalization during infancy (OR 2.20; 95%CI, 1.48–2.91). Nevertheless, some studies have not found the inverse association. For example, a 2015 study by Visness et al. found no association between cord blood 25(OH)D level and risk of childhood wheezing in two well-established U.S. birth cohorts [148]. While this important null study does not negate the prior studies showing an inverse association, it does challenge all investigators to identify possible

**FIGURE 105.2** Associations between cord blood 25-hydroxyvitamin D (25[OH]D) levels with probabilities of cumulative wheeze or incident asthma by age 5 years ( $n = 922$  children in New Zealand). The vertical lines denote serum 25(OH)D benchmarks (in ng/mL). Adapted from Ref. [146].

effect modifiers that might explain the discrepant results. In other words, what environmental and/or genetic differences were there between the different study populations that might explain these strikingly different results?

Along those lines, relatively few groups have examined the effect of vitamin D pathway-related polymorphisms on the association between vitamin D status and ARI. A 2014 systematic review by McNally et al. identified three eligible studies on VDR polymorphisms and severe RSV bronchiolitis [149]. Unfortunately, only two VDR polymorphisms were included in more than one study: FokI (rs2228570) and TaqI (rs731236). All three studies reported a positive association between the FokI minor allele and disease (OR 1.52, 95%CI 1.12–2.05). Although statistical power was limited, the genotype analysis suggested a dominant or incomplete dominance model with combined ORs for fF (OR 1.73, 95%CI 0.92–3.36) and ff (OR 2.24, 95%CI 0.98–5.14) compared to the FF genotype. By contrast, the authors did not observe an association between TaqI and severe RSV-bronchiolitis at the allele or genotype level. In another study, Randolph et al. reported on the association between vitamin D-binding protein (DBP) haplotypes and severe RSV bronchiolitis [150]. Briefly, the study involved 198 children hospitalized with RSV bronchiolitis in Boston (and their 333 parents) and then was validated in a larger sample from the Netherlands. The investigators found that GC1s haplotype carriage may increase the risk of RSV bronchiolitis and subsequent asthma development. They noted that this haplotype is associated with higher DBP levels, perhaps resulting in less freely available 25(OH)D. More recently, Zacharioudaki et al. reported a prospective case-control study of infants with bacterial ( $n = 40$ ) or viral ( $n = 52$ ) infection, and 40 age-matched healthy controls [151]; most of the infections were respiratory. Compared to controls, infants with viral infection were more likely to have TaqI polymorphism, t allele (OR 1.96; 95%CI, 1.1–3.58), while controls were more likely to have the haplotype Gc1F of VDBP (OR 2.7; 95%CI, 1.3–5.6); no significant differences were found for the bacterial infection group, nor CYP27B1 (rs10877012) for either the viral or bacterial groups.

Although all of these genetic findings require confirmation, they suggest that an improved understanding of the interplay between vitamin D status and vitamin D pathway-related polymorphisms may influence our interpretation of studies on vitamin D and ARI/wheezing. Likewise, failure to control, or otherwise account, for these genetic factors may tend to obscure real differences between groups. VDR polymorphism data are discussed further in Chapters 60 and 61 and DBP polymorphisms in [Chapters 7 and 60](#).

Finally, on a different genetic tangent, Colak et al. recently used Mendelian randomization (MR) in two population-based cohorts to examine the relation of low vitamin D status with a specific type of ARI, bacterial pneumonia [152]. With >110,000 individuals and up to 38 years follow-up, they discovered that low plasma 25(OH)D (<10 ng/mL) was associated—both observationally and genetically—with an increased risk of bacterial pneumonia. While not RCT-level evidence, this MR analysis suggests a causal inverse association. The application of MR analysis in studying the effects of vitamin D status across the lifespan is discussed in greater detail in Chapter 61.

## 4.2 Interventional studies on ARI

The first interventional studies on vitamin D supplementation and ARI emerged during the 1990s and early 2000s. For example, one study gave 600–700 IU of vitamin D daily from cod liver oil/multivitamin supplementation [153] while another gave 60,000 IU weekly from a vitamin D/calcium supplement [154]; both studies noted less ARIs among children receiving supplementation. Secondary analyses of two RCTs on vitamin D supplementation for bone health also suggested a possible antiinfective benefit [155,156]. Since these early efforts, dozens of RCTs have directly focused on the effect of vitamin D supplementation (vs. placebo) on the risk of ARI. Accordingly, it should now be possible to go beyond the epidemiological associations in the reviewed observational studies and start to draw causal inferences.

Unfortunately, the design and interpretation of RCTs on any nutrient [157], including vitamin D supplements [158], presents major challenges. In addition to traditional concerns about trial participants (e.g., age, baseline vitamin D status, race/ethnicity, body mass index, comorbidities, genetic factors) and sample size, vitamin D trials need to commit to an “optimal” *vitamin D regimen* (frequency, initial bolus dose or not, regular dose, and duration). Although RCTs typically assign a uniform dose to subjects (as compared to placebo), vitamin D trials probably would be more effective with an individualized approach that strived for an optimal level of serum 25(OH)D. Logistical challenges, however, preclude this approach because real-time measurement of baseline 25(OH)D levels is likely to reveal vitamin D deficiency, which would, for ethical reasons, require treatment with vitamin D, particularly in a trial of long duration; such a cointervention would seriously impair the ability of the RCT to demonstrate any vitamin D effects. Exclusion of all subjects with vitamin D deficiency would, of course, make it impossible to study the effect of vitamin D supplementation in that target

population! With regard to frequency, while daily dosing seems more physiologic, monthly dosing is likely to have better adherence, an important consideration in trials of many years duration. Likewise, RCTs probably need to be of sufficient duration for serum levels of 25(OH)D to stabilize and, consequently, for vitamin D to exert its full effect. Shorter trials (e.g., those <6 months) may indeed show clinical differences but they would do so despite a 2- to 3-month delay in the treatment group reaching the 25(OH)D level that might be necessary for the hypothesized benefits.

Another important consideration is the comparison group [158]. Is it a true placebo (i.e., no vitamin D supplement or change in sunlight exposure) or is it placebo with “allowance” of vitamin D usage (e.g., up to 800 IU/day)? The latter may be required for ethical reasons in trials of longer duration but would create a challenge if the lower dose is sufficient to obtain the hypothesized benefit? Does the trial report a vitamin D supplement versus placebo comparison but, in reality, the placebo group improves their vitamin D status outside of the trial protocol. This placebo group “contamination” is particularly challenging since participants can simply go out in the sun for 10–15 min a few times weekly and thereby create large amounts of vitamin D. Clearly, this presents a unique challenge when testing the therapeutic effects of a vitamin D supplement!

With these caveats in mind, the emergence of multiple RCTs on the effect of vitamin D supplementation on ARI risk led to multiple systematic reviews on the topic [8,159,160]. These reviews have consistently agreed that vitamin D supplements appear safe and well-tolerated. With regard to their effect on ARI risk, most review support benefits but also comment on the extreme heterogeneity across trials, most notably differences in baseline vitamin D status, the vitamin D regimen, and the comparison group. For example, the 2013 systematic review by Jolliffe et al. included 14 trials, with discordant results [8]; approximately half reported benefits while half did not. Given this heterogeneity, the authors did not pool the trials for meta-analysis. Jolliffe et al. called for additional RCTs, particularly in populations with a high prevalence of vitamin D deficiency at baseline, using doses sufficient to raise 25(OH)D levels to potentially beneficial levels, and with sufficient statistical power to detect subgroup effects.

The 2013 systematic review by Bergman et al. included 11 trials ( $n = 5660$ ) which they did meta-analyze [159]. The authors found evidence of clinically and statistically significant benefit, with a summary OR of 0.64 (95%CI, 0.49–0.84). However, as the figure clearly shows, the RCT results are quite heterogeneous. The authors explored these differences and found, for example, that the protective effect against ARI was larger in trials that used once-daily dosing compared to bolus doses

(OR 0.51 vs. 0.86, respectively;  $P = .01$ ). More recently, in 2021, Abioye et al. pooled multiple micronutrient trials in adults and found a modest overall protective effect against ARI [161]. The authors found that the benefit was greater when the diagnosis was based on clinical diagnosis or laboratory testing, rather than self-report, and that the optimal dosing regimen would be a daily dose of at least 2000 IU, with a smaller loading dose (<60,000 IU). They also found that vitamin D supplementation shortened the duration of ARI symptoms mildly, though the effect did not differ by dose. Taken together, multiple systematic reviews have clarified that while vitamin D supplementation might indeed lower the risk of ARI, this benefit may apply only to specific individuals on specific vitamin D regimens; other individuals, on other regimens, may not derive any benefit at all.

To better study this effect modification, it would be helpful to have individual participant data (IPD) from every relevant RCT and to then analyze the newly compiled dataset in ways that are not possible in a traditional meta-analysis where the unit of observation is the entire trial. For example, if one were interested in the effect of vitamin D supplements on participants with low baseline levels of 25(OH)D, an IPD meta-analysis would permit the analyst to include every participant with a low baseline level of 25(OH)D, across all trials, into this one subgroup of interest. In 2017, Martineau et al. presented the first results of such a project [162]. Briefly, IPD from 25 RCTs worldwide were combined into a dataset with 10,933 participants. The overall finding was a protective effect against ARI (OR 0.88, 95%CI 0.81–0.96), with marked heterogeneity across the trials ( $P < .001$ ). Prespecified subgroup analysis revealed that daily-or-weekly dosing (without bolus) provided benefit (adjusted OR 0.81; 95%CI, 0.72–0.91) while those receiving one or more bolus doses did not (adjusted OR 0.97; 95%CI, 0.86–1.10;  $P$  for interaction = 0.05). Among those receiving daily or weekly vitamin D, protective effects were stronger among those with baseline 25(OH)D < 10 ng/mL (adjusted OR 0.30; 95%CI, 0.17–0.53) compared to those with baseline levels  $\geq 10$  ng/mL (adjusted OR 0.75; 95%CI, 0.60–0.95;  $P$  for interaction = 0.006).

In 2021, the IPD meta-analysis was updated with more RCTs, including some that had been started long before the 2017 publication [163]. For example, a large trial from New Zealand compared bolus dosing (200,000 IU at baseline, then monthly 100,000 IU) versus placebo and, consistent with the 2017 conclusions, the bolus dosing regimen showed no ARI benefit [164]. Adding more bolus trials to the IPD meta-analysis will, of course, weaken the overall “composite” finding but it should have little impact on the finding that daily dosing appears beneficial. Indeed, the 2021 IPD meta-analysis, with 43 eligible trials ( $n = 48,488$ ), showed

that a slightly lower proportion of participants in the vitamin D supplement group had one or more ARIs than in the placebo group (OR 0.92; 95%CI, 0.86–0.99). Again, there was evidence of significant heterogeneity across the trials ( $P = .018$ ).

Of note, the 2021 IPD meta-analysis also added a large trial from Mongolia that compared weekly doses of 14,000 IU versus placebo in Mongolian children with low vitamin D status and, surprisingly, it found no significant ARI benefit [71]. While the explanation for the Mongolia trial results is unclear, one possibility is that the children were effectively receiving bolus doses (albeit weekly) given their young age and size. Perhaps they would have benefitted from a smaller daily dosing? Regardless, the inclusion of this large number of children with vitamin D deficiency contributed to the loss of baseline 25(OH)D level as a predictor of vitamin D supplement benefit [163].

The 2021 IPD meta-analysis affirmed the value (all ORs  $<0.80$ ) of daily dosing, at a daily dose equivalent of 400–1000 IU, for a duration of 12 months or less [163]. There also was evidence of enhanced benefit among younger participants (ages 1–15.9 years). The authors concluded that despite evidence of significant heterogeneity across trials, vitamin D supplementation was safe and reduced the risk of ARI compared with placebo. While the overall effect was modest (OR 0.92), the benefit among a subgroup of the enrolled participants receiving daily dosing was substantial.

Taken together, RCTs to date, while not uniform in their results, suggest that vitamin D supplementation really can lower the risk of ARI, particularly in those at low baseline 25(OH)D levels and when the supplement is taken daily without bolus. As more RCT results emerge in the literature, we hope to add the IPD of these trials to the ongoing IPD meta-analysis to further refine our understanding. Based on the trials to date, adding more bolus trials will push the overall composite finding (any vitamin D supplement) toward the null. One hopes, however, that trialists will be guided by a more “precision medicine” approach and that they will design trials that are the most likely to show benefit.

## 5. Vitamin D and asthma

### 5.1 Asthma pathogenesis

Given the early age of asthma onset [50,51], and growing evidence for the developmental origins of obstructive lung diseases [52,165], the potential role of maternal diet during pregnancy on the asthma risk of offspring continues to be an active area of research worldwide. However, while investigators have debated the possible role of micronutrient intake on asthma risk

for many decades, multiple reviews of diet and asthma—from 1997 to 2005—said nothing about vitamin D as a potential risk factor for asthma [80–82,166].

As discussed by Camargo et al. in their 2007 publication [77], epidemiologic data in the mid-2000s suggested a possible association between vitamin D deficiency and the asthma epidemic. For example, the prevalence of both conditions is higher in racial/ethnic minorities, obese individuals, and westernized populations. Moreover, a large cross-sectional study in 2005 had shown that vitamin D deficiency was correlated with lower pulmonary function, including forced expiratory volume in 1 s (FEV<sub>1</sub>) and forced vital capacity [83]. Of course, the causality of this cross-sectional association was uncertain; although low vitamin D status might cause asthma (or lower pulmonary function), it also was possible that individuals with asthma were less likely to exercise outdoors and that this and other lifestyle differences could have caused the vitamin D deficiency. Similarly, lingering concerns about the adverse effect of milk on asthma may have led some asthmatic individuals to avoid milk intake (a major dietary source of vitamin D in US children [77]), and this food avoidance also could create a spurious inverse association between vitamin D intake and asthma. Prospective studies (especially RCTs) would help to address these major methodological concerns. These studies would be challenging, of course, given the duration of follow-up required—e.g., until at least 5–6 years of age for a diagnosis of childhood asthma [50] and until late adolescence for lung development [84].

As noted earlier, the hypothesis that vitamin D deficiency may cause asthma—and that vitamin D supplements may prevent asthma—was disputed by Wjst, who repeatedly described vitamin D supplementation as an important *cause* of asthma [9,85,86]. The strongest support for this putative harm came from a large birth cohort in northern Finland [87]. In this 2004 publication, Hypponen, Wjst et al. reported that regular vitamin D supplementation ( $\geq 2000$  IU/d) in the first year of life increased the risks of developing atopy (OR 1.46), allergic rhinitis (OR 1.66), and asthma (OR 1.35), by age 31 years. For reasons that will be discussed later in this chapter, this finding may be related to the very high dose of vitamin D supplementation used in these infants (i.e., this may represent a dose-specific effect during a critical window). Regardless, this retrospective cohort study also was limited by the absence of data on maternal intake of vitamin D and the inability to control for major confounders. Furthermore, recall bias may have affected the ascertainment of early-life asthma and allergies.

Nevertheless, other contemporaneous European publications also have suggested that vitamin D supplements may increase asthma/allergy risk [88,89]. Gale

et al. studied child health outcomes in a UK birth cohort and found that higher levels of maternal 25(OH)D (measured at a median of 33 weeks gestation) were associated with an increased risk of atopic outcomes [88]. More specifically, children whose mothers had 25(OH)D levels in pregnancy  $>30$  ng/mL had an increased risk of eczema at 9 months (OR 3.26) and asthma at 9 years (OR 5.40), compared to children whose mothers had levels  $<12$  ng/mL. Unfortunately, this study also has several methodological limitations, including small numbers of outcomes and poor follow-up (e.g., only 30% at age 9 years); the authors appropriately called for confirmation of these associations in other studies. The UK findings were similar, however, to those of Back et al. in Sweden [89]. In this small cohort of 123 children, the investigators found higher age 6-year prevalence of atopic conditions among children who had taken vitamin D supplements during infancy. In another northern European study, Hansen et al. in Denmark, investigators reported that high maternal 25(OH)D levels during pregnancy (i.e.,  $\geq 50$  ng/mL) may have been associated with offspring having a higher risk of asthma outcomes during adulthood, as compared to children of women with maternal levels of  $<20$  ng/mL [90]. More recently, Nwaru et al. in Finland reported that increased vitamin D intake (particularly at ages 1 and 2 years), may increase the risk of childhood asthma [91]. In sum, although all of these European studies acknowledge methodological problems, the combined data do raise important potential safety concerns about high-dose vitamin D supplementation in late pregnancy or infancy.

Concerns about vitamin D in general are mitigated by several epidemiologic studies showing that vitamin D has no apparent association with the development of true childhood asthma. As described in the section on "Vitamin D and ARI," birth cohorts in both Boston [77] and Scotland [79] found an inverse association between maternal intake of vitamin D during pregnancy and risk of recurrent childhood wheezing, which is not synonymous with true asthma. The Scottish investigators reported that lower vitamin D intake during pregnancy was associated with a borderline significant decrease in bronchodilator response ( $P = .04$ ), but there was no association with doctor-diagnosed asthma or other asthma-related outcomes, such as spirometry or exhaled nitric oxide concentration [79]. Both studies were limited, however, by their estimation of vitamin D status from oral intake only. Thus, the unique contribution of the New Zealand birth cohort [146] was the concurrent demonstration that low cord blood 25(OH)D levels were associated with an increased risk of ARIs and childhood wheezing, but had no association with the risk of current asthma at age 5 years (Fig. 105.2). The lack of association between vitamin D and incident

asthma was present for both atopic asthma and non-atopic asthma, with atopy defined by skin-prick testing for common allergens at age 15 months.

Since the publication of these three birth cohort studies [77,79,146], many birth cohorts from around the world have examined these same questions, using different measures of vitamin D status and different definitions of "asthma" (ranging from recurrent wheezing during early childhood to an actual confirmed diagnosis by a physician). As previously discussed, two systematic reviews did not find an association between maternal intake of vitamin D during pregnancy and the risk of offspring asthma [143,145]. Based on these null findings, and notwithstanding the compelling rat model data on lung development (chapter Section 3), there is little epidemiologic support for vitamin D supplementation during pregnancy as an effective strategy for the primary prevention of childhood asthma.

While this discussion has focused heavily on childhood asthma, researchers over the past few years have started to study a possible link between adult vitamin D status and adult-onset asthma. For example, Mai et al. reported evidence from a large population-based cohort in Norway and found that vitamin D status, as measured by serum 25(OH)D level, was unrelated to adult-onset asthma in most adults [92]. On the contrary, these investigators found that a higher intake of cod liver oil, a traditional source of vitamins A and D in Nordic countries, was associated with an increased risk of developing adult-onset asthma [93]; the authors speculated that this excess risk may have been due to the high vitamin A content of the cod liver oil preparation.

As noted earlier, the link between vitamin D and asthma also has been examined using genetic data. Although preliminary evidence from two family-based studies suggested that specific VDR gene polymorphisms were associated with asthma among North American children and adults [10,11], the results were inconsistent across cohorts/studies and were not confirmed [12,13]. A 2009 study by Bosse et al. reported that several genes involved in the vitamin D pathway (e.g., *IL10*, *CYP24A1*, *VDR*) had "modest levels of association" with asthma and atopy but the specific SNPs, or the orientation of the risk alleles, were different between populations [94]. In a 2016 systematic review by Han et al., the authors identified nine eligible studies (2116 asthma patients and 1884 healthy controls) that examined the association between VDR polymorphisms and asthma risk [95]. The meta-analysis showed that rs2228570, rs7975232, rs731236 and rs3782905 gene polymorphisms in VDR were associated with increased susceptibility to asthma. In another systematic review, Zhao et al. also focused on VDR polymorphisms but stratified their meta-analysis by ethnicity [96]. These authors

report significant associations for FokI (rs2228570) among whites, and ApaI (rs7975232) among Asians; other gene polymorphisms were not significantly associated. With regard to *DBP* (GC) polymorphisms, a paper by Navas-Nazario et al. found that, compared with the wild-type genotype DT/DT (Gc1f/Gc1f), the ET/ET (Gc1s/Gc1s) genotype of *DBP* was less associated with childhood asthma [97]. Recently, in 2020, Makoui et al. reported a meta-analysis, based on 17 case-control studies, with a goal of identifying whether *VDR* gene polymorphisms play a role in risk of asthma [98]. The results of the pooled analysis revealed significant “protective” associations between FokI SNP and TaqI polymorphisms with asthma risk. Moreover, subgroup analyses showed race/ethnicity influences asthma risk in Asian, African, and American populations.

The implications of these genetic findings for the primary prevention of asthma remain unclear and require further investigation. *VDR* polymorphisms are discussed further in Chapters 60 and 61 and *DBP* polymorphisms in Chapters 7 and 60. On a final genetic tangent, Hysinger et al. reported an MR analysis that found that low vitamin D status is unlikely to be causative for childhood asthma [99].

Taking all of this evidence under consideration, it seems unlikely that vitamin D deficiency during pregnancy (or early infancy) is a major contributor to the current global asthma epidemic. Nevertheless, if a modest association exists between vitamin D deficiency and incident asthma, it might be mediated through increased risk of specific types of ARIs, or perhaps a high frequency of ARIs, in early life. In a 2008 paper from the Childhood Origins of Asthma (COAST) birth cohort in Wisconsin, Jackson et al. [100] reported that wheezing rhinovirus illness during infancy strongly predicted the development of asthma at age 6 years. A 2019 study in a large cohort of children with a history of severe bronchiolitis confirmed that RV bronchiolitis conveys increased risk when combined with atopy [101]. Given the connection between vitamin D deficiency and ARI risk (see earlier section), and inconsistent laboratory data on the effect of vitamin D on rhinovirus replication [102,103], it remains possible that “healthy” levels of vitamin D might prevent some cases of rhinovirus ARI and thereby lower future risk of incident asthma. Unfortunately, the COAST study also was the birth cohort where cord blood 25(OH)D levels were unrelated to either childhood wheezing or age 6-year asthma [148]; repeat 25(OH)D levels later in childhood also yielded nonsignificant associations in this Wisconsin cohort (Camargo et al., unpublished data). While the vitamin D-ARI-asthma hypothesis merits further investigation, it does not look promising. Moreover, this speculation must be balanced against several studies suggesting that excessive vitamin D supplementation during pregnancy and infancy may increase

the risk of asthma and allergies in some children, either during childhood or early adulthood [87–90].

While this evidence base was building, several large RCTs were launched to better examine the hypothesis that prenatal vitamin D supplementation might prevent childhood asthma. A 2016 systematic review by Vahdaninia et al. [104] identified three eligible RCTs on this topic, with the important caveat that all three trials used *childhood wheezing by age 3 years* as a proxy for asthma. Pooled analysis of the 1387 participants in the two major trials—one by Chawes et al. in Denmark, which compared 2400 IU/day versus placebo [105], and the other by Litonjua et al. in the United States, which compared 4000 IU/day versus placebo [106]—showed that daily vitamin D supplementation during pregnancy significantly reduced risk of childhood wheezing (RR 0.80; 95%CI, 0.66–0.97). The inclusion of the smaller RCT by Goldring et al. [107], which involved a more complex study design, did not materially affect the results (RR 0.82; 95%CI, 0.68–0.99). The authors of the systematic review concluded that daily vitamin D supplementation during pregnancy appears to protect against the development of childhood wheezing but cautioned that “early childhood wheeze is not the same as asthma.” They called for longer-term follow-up of these RCT cohorts to establish the efficacy of prenatal vitamin D supplementation in the primary prevention of actual asthma.

Indeed, with the passage of time, both the Danish and USA trials have reported on the impact of vitamin D supplementation during pregnancy on the risk of asthma at age 6 years. Neither trial found an association between the prenatal intervention and asthma risk [108,109]. The consistency of these findings is striking, with evidence of benefit in early life (presumably ARI-related wheezing) but no apparent impact on actual childhood asthma. Recently, Kihltila et al. reported a novel twist on the recurrent wheezing results [110]. Briefly, they reported that maternal 17q21 genotype had an important influence on the protective effect of prenatal vitamin D supplementation on offspring recurrent wheeze in both trials, with significantly reduced risk among mothers with low-risk GG or GC genotype but no such difference among offspring of mothers with the high-risk CC genotype. This novel finding merits further investigation.

Finally, although a fourth RCT did not meet the eligibility criteria of the Vahdaninia systematic review, this work from New Zealand provides additional insights [111]. Briefly, Grant et al. enrolled 266 pregnant women who were randomized to three groups: placebo, lower-dose vitamin D (1000 IU daily), and higher-dose vitamin D (2000 IU daily). Unlike the other three RCTs, which stopped the vitamin D intervention at birth [106,107] or at 1 week postpartum [105], the New Zealand trial

continued the vitamin D intervention in the infants for 6 months postpartum. In correspondence to the randomly assigned group of the mother, infants were assigned to placebo, 400 IU/day, and 800 IU/day. In a post hoc analysis of primary care visits from birth until age 18 months, the higher-dose vitamin D group experienced significantly less total ARI visits per child than those in the placebo group. Although reported in this section of the chapter—because of its pregnancy/infancy design—this New Zealand RCT focused on ARI; these data contributed to the previously discussed IPD meta-analyses on vitamin D supplementation and risk of ARI [162,163].

## 5.2 Asthma control, including exacerbations

Although improved vitamin D status does not appear to affect the risk of incident asthma, it could have an important role in asthma management among those who already have developed the disease. In other words, vitamin D may have little role in disease prevention (primary prevention) but an important role in disease modification (secondary prevention). The potential benefits are based on two interrelated concepts: (1) responsiveness to corticosteroids and (2) risk of exacerbations.

### 5.2.1 Responsiveness to corticosteroids

With regard to corticosteroids, most individuals with asthma respond well to inhaled corticosteroids, with demonstrated reductions in symptoms and serious exacerbations and improved pulmonary function and asthma-related quality of life [43,44]. For these reasons, asthma guidelines uniformly consider inhaled corticosteroids the preferred long-term control medication for asthma. Nevertheless, asthma control on even “optimal” controller therapy often leaves room for improvement [112]. This is particularly true in a relatively small subset of asthma patients with corticosteroid resistance [113]. In 2006, Xystrakis et al. reported the effect of calcitriol treatment in this asthma subgroup [114]. The investigators administered oral 1,25(OH)<sub>2</sub>D (0.5 µg/day for 7 days) to a small group of healthy individuals and corticosteroid-resistant asthma patients and found that the intervention enhanced subsequent responsiveness to dexamethasone due to induction of interleukin (IL)-10. The investigators concluded that vitamin D could potentially increase the therapeutic response to corticosteroids in otherwise resistant asthma patients.

Over the past 15 years, several groups have built on this innovative work. In 2010, for example, Sutherland et al. studied 54 adults with asthma to determine the relation of serum 25(OH)D levels to asthma phenotype and corticosteroid response [115]. In this cross-

sectional study, patients with lower serum 25(OH)D levels were more likely to have impaired lung function and increased airway hyper-responsiveness. Among the subset of patients not on inhaled corticosteroids, lower 25(OH)D levels were correlated with lower corticosteroid response (as measured by dexamethasone-induced expression of mitogen-activated protein kinase phosphatase (MPK)-1 by peripheral blood cells); this finding was not seen among patients on inhaled corticosteroids. Searing et al. studied similar issues in 100 asthmatic children [116]. In the cross-sectional part of their study, lower serum 25(OH)D levels were associated with greater corticosteroid use and worse airflow limitation. Moreover, the investigators found the amount of MPK-1 and IL10 mRNA induced by dexamethasone plus 1,25(OH)<sub>2</sub>D was significantly greater than that induced by dexamethasone alone ( $P < .01$ ). In an experimental model of corticosteroid resistance in which dexamethasone alone did not inhibit T-cell proliferation, the addition of 1,25(OH)<sub>2</sub>D caused significant dose-dependent suppression of cell proliferation. In 2012, Goleva et al. extended this research by demonstrating significant associations between serum 25(OH)D levels and corticosteroid requirement and in vitro responsiveness to corticosteroids in asthmatic children but not asthmatic adults [117]; likewise, 25(OH)D was associated with IgE in children but not in adults. In 2015, Chambers et al. identified both IL-17A<sup>high</sup> and IFN-γ<sup>high</sup> immunophenotypes in patients with corticosteroid-resistant asthma and showed that calcitriol potentially improves the clinical response to corticosteroids through reduction of IL-18A production and enhancement of corticosteroid-induced IL-10 [118]. The authors suggest that these laboratory findings might help to identify vitamin D responder immunophenotypes. Recently, Jiang et al. used a proteomic approach to identify biomarkers in a small sample and found that increased DBP might be a useful biomarker for predicting corticosteroid-resistance in asthma patients [119]. While this final study was quite small and exploratory, the authors' convergence on DBP provides another interesting link between vitamin D and corticosteroids in asthma.

In the epidemiologic realm, several studies have identified a link between vitamin D status and inhaled corticosteroid requirements and effectiveness. For example, in 2012, Wu et al. reported the association between baseline vitamin D status and the effect of inhaled corticosteroid treatment on lung function in children [120]. The investigators analyzed data from 1024 asthmatic children in the Childhood Asthma Management Program (CAMP) where 10% had baseline 25(OH)D levels <20 ng/mL, 25% were 20–30 ng/mL, and 65% were >30 ng/mL. In the inhaled corticosteroid treatment group, prebronchodilator FEV1 increased from randomization to 12 months by 140 mL in the <20 ng/

mL group, by 330 mL in the 20–30 ng/mL group, and by 290 mL in the >30 ng/mL group ( $P = .007$ ). The authors recommended monitoring 25(OH)D levels when treating children with persistent asthma with inhaled corticosteroids.

In this context, in 2014, Castro et al. reported RCT results on the effect of vitamin D supplementation in adults with symptomatic asthma and baseline 25(OH)D  $< 30$  ng/mL [121]. The 408 subjects were randomly assigned to either vitamin D (100,000 IU bolus, then 4000 IU/day for 28 weeks,  $n = 201$ ) or placebo ( $n = 208$ ), with both groups also receiving an inhaled corticosteroid, ciclesonide 320  $\mu$ g daily. If asthma control was achieved after 12 weeks, ciclesonide was tapered per protocol. The primary outcome (asthma treatment failure) will be addressed later in this section (along with other studies of vitamin D and asthma exacerbation) but one of the secondary outcomes is relevant here. Briefly, the RCT revealed that the average overall dose of the inhaled corticosteroid required to maintain asthma control was lower in the vitamin D group than in the placebo group. While the average  $\mu$ g difference was admittedly small, one wonders what the RCT results might have looked like in adults (or children) with lower baseline 25(OH)D levels and higher corticosteroid resistance? Moreover, building on the emerging evidence against the bolus dosing for ARI prevention, what impact did the initial 100,000 IU bolus have on these study results? Regardless, the reported finding is consistent with a growing body of evidence that supports a clinically significant hormonal interaction between corticosteroids and vitamin D in at least some patients with asthma.

### 5.2.2 Asthma exacerbations

With regard to asthma exacerbations, it is important to remember that viral ARIs, particularly human rhinovirus, are associated with most exacerbations [48,49]. While adults typically experience 2 to 4 upper ARIs per year, young children experience 6 to 10 per year [41]. Furthermore, individuals with asthma may be more susceptible to ARI and have an increased frequency of lower respiratory tract symptoms of higher severity and duration [122]. As described in more detail in Chapters 94–99, the role of vitamin D in innate immune responses may explain a predisposition to ARI and asthma exacerbation in vitamin D deficient populations.

As discussed earlier in this chapter, there is substantial evidence of a “protective” association between vitamin D and ARI in a subset of the general population, with RCT evidence suggesting the specific individuals (e.g., low baseline 25(OH)D levels, children) and vitamin D regimens (e.g., daily dosing without any bolus) that are most likely to demonstrate benefit. To date, however,

there are substantially less data on this vitamin D-ARI link among asthmatic individuals. In a 2009 publication based on nationally-representative data from NHANES-III [7], the association between serum 25(OH)D levels ( $<10$  ng/mL versus  $\geq 30$  ng/mL) and upper ARI was much stronger among individuals with asthma (OR 5.67) compared to those without asthma (OR 1.24;  $P$  for interaction = 0.007). Consistent findings were reported from a cross-sectional study by Brehm et al. on 616 Costa Rican children [123]. In multivariable models, lower serum 25(OH)D levels were associated with higher total IgE and eosinophil count, increased airway responsiveness, higher likelihood to have been hospitalized for asthma in the past year, and a higher likelihood of having used an antiinflammatory medication in the past year. Although these findings sound compelling, the cross-sectional design leaves room for reverse-causality. While upper ARIs are unlikely to cause a lasting reduction in serum 25(OH)D level, one might reasonably ask if children with severe persistent asthma are more likely to stay indoors—and, as a result, have lower serum 25(OH)D levels?

To that end, Brehm et al. examined the *longitudinal* association between serum 25(OH)D levels and the risk of severe asthma exacerbations in the CAMP study [124]. Children with low baseline 25(OH)D levels ( $<30$  ng/mL) were more likely to have a severe asthma exacerbation over a 4-month follow-up period (OR 1.5; 95%CI 1.1–1.9). As noted earlier, the original CAMP trial involved randomization to different asthma treatments and the investigators reported a “protective” association between 25(OH)D level and severe exacerbation in children randomized to budesonide (OR 1.8; 95% 1.0–3.2), as well as those randomized to either placebo or nedocromil (OR 1.3; 95%CI, 1.0–1.9). These observational data support the potential role of vitamin D as an adjunct treatment for asthmatic children with low baseline 25(OH)D levels.

Over the past decade, epidemiology research on vitamin D and asthma management continues to support these general observations but it also has expanded to other areas of asthma control. For example, Brumpton et al. examined the association between 25(OH)D levels and lung function decline in 395 Norwegian adults with asthma [125]. The investigators found that low 25(OH)D levels ( $<20$  ng/mL) were weakly associated with more lung function decline in the entire sample, but that there were stronger associations among specific asthma subgroups (i.e., never smokers and those not using inhaled corticosteroids). In a subsequent paper, looking at 25(OH)D level, vitamin D supplement, and asthma control [126], the authors reported little evidence that, among adults with asthma, having a low 25(OH)D level of being a nonuser of vitamin D supplement was associated with poor asthma control. While these cohort

findings require replication, they are cited to demonstrate some of the newer areas of vitamin D-asthma research.

A more conventional approach to improving asthma control is to reduce exacerbations and, for that, there now are several RCTs on supplementation with vitamin D versus placebo among asthmatic individuals of all ages. For example, in 2015, Martineau et al. reported an RCT where 250 adults were given six 2-monthly doses of 120,000 IU of vitamin D or placebo over 1 year [127]. The intervention did not influence time to first severe exacerbation or first upper ARI; indeed, the investigators did not find any clinically important effect of vitamin D for any secondary outcome. Moreover, these results were not modified by baseline 25(OH)D level or genotype.

The previously introduced RCT by Castro et al. also addressed the impact of vitamin D on the clinical course of adults with asthma [121]. In this 2014 publication, the primary outcome was first “asthma treatment failure”, which was a composite outcome of decline in lung function and increases in use of beta-agonists, systemic corticosteroids, and health care. As the primary outcome, the authors focused on this result which was completely null (adjusted hazard ratio 0.9, 95%CI 0.6–1.3,  $P = .54$ ). However, the investigators also reported an outcome of greater relevance to this discussion, the number of asthma exacerbations over the entire 28-week study period. For that outcome, the vitamin D group had 0.26 events per person-year while the placebo group had 0.40 (adjusted hazard ratio 0.63, 95%CI 0.39–1.01,  $P = .05$ ). Thus, despite the initial 100,000 IU bolus and enrollment of a relatively broad panel of adults, this reportedly “null” RCT provided evidence that daily vitamin D supplementation may lower the risk of exacerbations in at least some adults with asthma. In a recently published post hoc analysis by the investigators [128], Jiao et al. report statistically significant decreases in asthma exacerbation event rates among subjects without sinonasal disease (adjusted RR 0.3, 95%CI 0.1–0.7,  $P = .01$ ) but warned of a possibly higher rate of exacerbation among black asthmatic adults with sinonasal disease (adjusted RR 2.0, 95%CI 0.7–5.5,  $P = .17$ ). The inclusion of these and other data into our ongoing IPD meta-analyses [162,163] could help to determine if the nonsignificant signal among blacks is a chance finding or of actual concern.

In a 2015 systematic review on RCTs of vitamin D supplementation and ARI in children, Xiao et al. reported favorable results for asthma exacerbation [129]. They included seven eligible trials and provided a summary estimate for ARI that, while not statistically significant (RR 0.79, 95%CI 0.55–1.13), had a point estimate comparable to that in prior studies. More importantly, the pooled data from the two trials with asthma data

[130,131], which both used daily dosing, showed a dramatic reduction in exacerbation risk (RR 0.26; 95%CI, 0.11–0.59). The authors concluded that their findings did not support the routine use of vitamin D supplementation for ARI prevention in healthy children but that supplementation was of likely benefit among children with asthma. In view of the IPD meta-analysis data regarding ARI [162,163], it also seems reasonable to surmise that vitamin D supplementation, when used, should avoid bolus dosing.

In 2017, Jolliffe et al. published an IPD meta-analysis of RCTs that examined the effect of vitamin D supplementation on the risk of asthma exacerbations [132]. Briefly, eight RCTs were included, with a total of 1078 participants. Vitamin D supplementation reduced the rate of asthma exacerbation requiring treatment with systemic corticosteroids among all participants (adjusted IRR 0.74; 95%CI, 0.56–0.97). Subgroup analyses suggested that protective effects may have been larger in participants with baseline 25(OH)D < 10 ng/mL (adjusted IRR 0.33; 95%CI, 0.11–0.98) than among those with higher levels (adjusted IRR 0.77; 95%CI, 0.58–1.03) but the formal test for interaction was not significant ( $P$  for interaction = 0.25). Although statistical power was limited, the IPD meta-analysis did not suggest that daily versus bolus dosing mattered.

In 2020, Forno et al. published an RCT looking at whether vitamin D supplementation reduces the risk of severe childhood asthma exacerbations [133]. Briefly, participants were randomized to 4000 IU/day or placebo and there was no difference in exacerbation rates. A secondary outcome was the effect of the supplement on ICS dose and no differences were observed. The participants were described as having “low vitamin D levels” (i.e., <30 ng/mL), with baseline values of approximately 23 ng/mL; participants with truly low levels were excluded.

In 2021, Jat et al. reported another RCT of vitamin D supplementation in children with asthma [134]. The 250 Indian children received 1000 IU daily for 9 months or a similar-looking placebo and, again, there was no evidence of improved asthma control. Baseline 25(OH)D levels were <15 ng/mL in this trial, with a rise to 18 ng/mL in the intervention group. The explanation for the discordant results is not yet clear. It will be helpful to add these trial data to the ongoing IPD meta-analyses to pursue potential effect modifiers.

## 6. Vitamin D and Copd

### 6.1 COPD pathogenesis and progression

While many studies have looked at the potential role of vitamin D in the etiology of asthma, there are much

less data on whether vitamin D is associated with the risk of developing COPD. An early (2013) review article by Janssens et al. listed several biologically-plausible mechanisms by which low vitamin D status might contribute to COPD, and summarized studies showing that COPD patients tend to have low vitamin D status [135]. They acknowledged the nonetiologic explanations for this cross-sectional finding (e.g., older individuals with COPD may simply spend less time outdoors or eat differently than their healthier, non-smoking counterparts). While cohort studies of 25(OH)D status and lung function could better address this reverse causality, they still may be subject to significant confounding by smoking and exercise [136], which have their own complex associations with other lifestyle factors and diseases. Moreover, smoking status might modify the association between vitamin D and lung health, or, stated differently, vitamin D might offset some of the adverse effects of smoking on the lung [137,138]. In light of the relatively sparse data, the 2013 review called for large population-based and clinical cohort studies to investigate whether vitamin D status influences the risk of developing COPD, decline in lung function, or AECOPD frequency. (AECOPD will be addressed in the next section).

In 2014, Afzal et al. published the first population-based study on vitamin D status and risk of COPD [139]. Briefly, plasma 25(OH)D levels were measured in the Copenhagen City Heart Study ( $n = 10,116$ ) and the Copenhagen General Population Study ( $n = 8391$ ); in the former study, up to three spirometry measurements were taken during approximately 20 years of follow-up, which permitted analysis of lung function decline. The investigators found that low 25(OH)D levels were associated with faster lung function decline and lower lung function. Moreover, low baseline 25(OH)D levels were associated with a higher risk of incident COPD. These Danish results are striking but await replication in other large prospective cohorts. For example, in the Nurses' Health Study ( $n = 64,494$  women) and Health Professionals Follow-up Study ( $n = 45,421$  men), we have not found any association between vitamin D status and risk of incident COPD (Camargo et al., unpublished data).

In the genetic realm, several studies over the past 25 years have suggested a possible association between DBP polymorphisms and COPD. In 2015, this topic was the focus of several meta-analyses from China. For example, Xiao et al. identified seven eligible studies ( $n = 1475$ ) and found that GC1f was a risk factor for COPD in Asians, whereas GC1f was a protective factor against COPD in whites [140]. Chen et al. identified eight eligible studies ( $n = 2216$  patients) and found, among Asian patients only, that the GC1f was a risk factor, while the GC1S and GC2 were protective [141]. Xie

et al. identified 12 studies ( $n = 2937$ ) and found, among Asians only, that GC1f was a risk factor, while GC2 was protective [142]. Clearly, more data are needed to clarify these disparate findings, with particular attention to the role of race/ethnicity. DBP polymorphism data are discussed further in Chapters 7 and 60.

To address the hypothesis that low vitamin D status might increase lung function decline among patients with prevalent COPD, Kunisaki et al. examined serum 25(OH)D levels and *longitudinal* lung function decline in the Lung Health Study three cohort [167]. The investigators performed a nested (prospective) case-control study involving 196 COPD patients with either rapid (case) or slow (control) decline in FEV<sub>1</sub> over approximately 6 years of follow-up. Despite rapid and slow decliners experiencing strikingly different rates of FEV<sub>1</sub> decline ( $-151$  vs.  $0$  mL/year,  $P < .001$ ), there was no significant difference in baseline 25(OH)D levels between the two groups ( $25.0$  vs.  $25.9$  ng/mL,  $P = .54$ ). While these findings require replication, they suggest that vitamin D status is not associated with lung function decline among patients with COPD. By contrast, a 2015 study by Persson et al. in Norway followed 426 COPD patients every 6 months for several years [78]. The one-third of the patients with baseline 25(OH)D  $< 20$  ng/mL tended to experience a greater decline in both FEV<sub>1</sub> and FVC, compared to patients with higher levels; for FEV<sub>1</sub>, this difference was statistically significant only for the subset of COPD patients with baseline 25(OH)D levels  $< 10$  ng/mL.

In a relevant study, Sluyter et al. examined the effect of monthly vitamin D supplementation on lung function in a large New Zealand RCT of older adults [168]. Briefly, the intervention group received 100,000 IU monthly, while the comparison group received placebo. There were no significant lung function improvements in the total sample, vitamin D deficient participants, or those with asthma/COPD. However, among ever smokers ( $n = 217$ ), the mean (95%CI) FEV<sub>1</sub> increase in the vitamin D versus placebo was 57 [4–77], [79–86], [143–166] mL ( $P = .04$ ). FEV<sub>1</sub> improvements were largest among vitamin D deficient ever-smokers with asthma COPD ( $n = 60$ ): 160 (53, 268); ( $P = .004$ ). Thus, vitamin D supplementation did not benefit everyone but benefitted ever-smokers, especially those with vitamin D deficiency or asthma/COPD.

In summary, while many COPD patients have vitamin D deficiency [135] and may warrant vitamin D supplementation for general health reasons, the role of vitamin D supplementation in the primary prevention of COPD awaits more robust data from additional prospective cohort studies and, if warranted, future RCTs. Likewise, the role of vitamin D supplementation on the progression of lung function decline in COPD patients requires further study.

## 6.2 Acute exacerbations of COPD

Similar to asthma exacerbations, most AECOPDs are caused by common respiratory viruses [57]. Since vitamin D-mediated immune mechanisms appear to play a role in the prevention of viral ARI, vitamin D supplementation might be helpful against AECOPD. However, AECOPD is a more complicated phenomenon than asthma exacerbation. For starters, AECOPD often involve both viruses and bacteria [57]. Moreover, the typical COPD patient is older and more likely to suffer from other relevant smoking-related comorbidities, such as cardiovascular disease [169]. Nevertheless, the question remains: does vitamin D supplementation lower the risk of AECOPD?

In 2012, Kunisaki et al. analyzed data from an azithromycin trial of exacerbation-prone patients with COPD to examine the longitudinal association between baseline 25(OH)D levels and the risk of AECOPD over 1 year [170]. Contrary to their hypothesis, baseline 25(OH)D levels were unrelated to the risk of AECOPD in their observational study of this high-risk population. Similarly, null findings were reported in a 2014 study by Puhan et al. from the Netherlands and Switzerland [171] and in the previously cited 2015 study by Persson et al. in Norway [78]. Taken together, these observational studies do not support the role of vitamin D supplementation in the prevention of AECOPD.

In 2012, however, Lehouck et al. published the first major RCT on the effect of vitamin D supplementation on the risk of AECOPD [172]. This Belgian trial involved 182 patients with moderate to very severe COPD and a history of recent exacerbations; subjects were randomly assigned to a monthly dose of vitamin D (100,000 IU) or placebo for 1 year. The primary outcome was time to first AECOPD and the results were null (hazard ratio 1.1, 95%CI 0.82–1.56,  $P = .41$ ), as were several secondary outcomes, including AECOPD rates, FEV<sub>1</sub>, and hospitalization. However, a post hoc analysis of the 30 patients with baseline 25(OH)D < 10 ng/mL showed a significant AECOPD reduction in the vitamin D group (RR 0.57, 95%CI 0.33–0.98,  $P = .04$ ). In a separate post hoc analysis of 50 participants, Hornikx et al. examined the potential effect of vitamin D intervention on pulmonary rehabilitation outcomes [173]. Compared to the placebo group, patients taking monthly boluses of vitamin D had significantly larger improvements in inspiratory muscle strength and maximal oxygen uptake, while quadriceps strength and 6-minute walking distance did not differ between groups. While not directly related to AECOPD, the rehabilitation findings, if replicated, suggest another way in which vitamin D supplementation might play a role in the long-term management of patients with COPD. For further discussion of the effects of vitamin D on muscle function, please see [Chapters 29 and 38](#).

In 2015, Martineau et al. reported the results of another important RCT in the vitamin D-AECOPD literature [174]. In this UK trial, 240 patients were given six 2-monthly doses of 120,000 IU of vitamin D or placebo over 1 year. Similar to the Lehouck trial [172], the bolus intervention did not influence time to first AECOPD or first upper ARI. However, also similar to the Lehouck trial, a prespecified subgroup analysis showed that vitamin D was protective in patients with baseline 25(OH)D < 20 ng/mL (hazard ratio 0.57, 95%CI 0.35–0.92,  $P = .02$ ) but not in those with higher baseline levels ( $P$  for interaction = 0.02). On the other hand, baseline 25(OH)D level did not modify the effect of the bolus vitamin D dosing on the risk of first upper ARI. The reason for the disconnect between ARI and AECOPD is not yet clear but the authors speculated, based on exploratory analyses, that vitamin D might have attenuated the potential for an upper ARI to precipitate AECOPD.

In 2019, Jolliffe et al. published an IPD meta-analysis of RCTs that examined the effect of vitamin D supplementation on the risk of AECOPD [175]. The analysis included only four RCTs ( $n = 560$ ), with IPD obtained from three RCTs ( $n = 469$ ). Although supplementation did not effect the overall rate of moderate/severe AECOPD (adjusted IRR 0.94; 95%CI, 0.78–1.13), a prespecified subgroup analysis revealed protective effects among participants with baseline 25(OH)D levels of < 10 ng/mL (adjusted IRR 0.55; 95%CI, 0.36–0.84) but not those with higher levels (adjusted IRR 1.04; 95%CI, 0.85–1.27;  $P$  for interaction = 0.015). Again, as with vitamin D for the prevention of asthma exacerbation, bolus dosing did not appear to matter.

Since the publication of this IPD meta-analysis, Rafiq et al. have published an important RCT on vitamin D [176]. They enrolled 155 COPD patients with baseline 25(OH)D levels < 20 ng/mL and allocated them to either vitamin D 16,800 IU weekly or placebo for 1 year. Briefly, the intervention did not reduce AECOPD. In a prespecified subgroup analysis of 31 participants with baseline levels between 6 and 10 ng/mL, no significant benefit was found (IRR 0.91; 95%, 0.43–1.93). This result differs from that of the three trials in the IPD meta-analysis and, once again, suggests the potential value of including these new data in the ongoing IPD meta-analysis to help understand potential effect modifiers.

On the other hand, Camargo et al. performed a post hoc analysis of data from a large RCT of older adults in New Zealand to examine the effect of monthly dosing on the risk of either asthma or COPD exacerbation [177]. Overall, the authors found that vitamin D supplementation did not affect exacerbation risk (HR 1.08; 95%CI, 0.84–1.39) but, among those with baseline 25(OH)D < 10 ng/mL, the HR was 0.11 (95%CI, 0.03–0.51;  $P$  for interaction = 0.001).

Taken together, the vitamin D-COPD literature is at an earlier stage of development than that on ARI, childhood wheezing, and asthma. Nevertheless, there are sufficient positive findings to warrant further study, particularly on the effect of vitamin D supplementation on AECOPD risk. While vitamin D will not help all patients with COPD, it seems likely that this safe and inexpensive intervention will help selected patients with COPD. Further studies are needed to try to identify this vitamin D-responsive patient group.

## 7. Potential mechanisms

In addition to the likely role of vitamin D in lung development (see [Section 4](#) of this chapter), vitamin D also is known to have myriad effects on the immune system. Briefly, there now is substantial evidence that vitamin D has important roles in both the innate and adaptive immune systems. This enormous topic is covered in detail in other dedicated parts of [Section 11](#) (Chapters 94–96).

Moreover, vitamin D appears to influence the development of several atopic/allergic diseases, including atopic dermatitis, food allergy, and allergic rhinitis [178,179]. Given the extraordinary growth of research in these topics, interested readers are referred to the cited articles for further details. Briefly, however, there are studies to suggest that vitamin D deficiency during pregnancy or infancy increases the risk of each of these disorders, while other studies suggest that higher vitamin D status confers increased risk—or that there is no association at all! To date, few RCT results are available to test if vitamin D supplementation can prevent any of these disorders, but emerging trials suggest that vitamin D supplementation may help to prevent sensitization to common allergens [180] and this would presumably interrupt the pathway to actual allergic disease. Likewise, for specific patient subgroups, there already are RCT results that support vitamin D supplementation for disease modification (e.g., vitamin D for winter-related AD [181,182]). Along those lines, the 2006 RCT by Byremo et al. deserves mention [183]. Although the investigators did not mention vitamin D in their article, they demonstrated that moving from Norway to sunny Gran Canary appeared to benefit patients with severe AD, including significant decreases in bacterial skin colonization with *S. aureus*. Whether sunlight has distinct effects, beyond vitamin D synthesis, is another promising topic for future research.

Clearly, there is a complex connection between vitamin D and the different atopy/allergy disorders and attempts to describe the vitamin D hormone as “good” or “bad” for a specific atopic disorder is far too simplistic for the complexity of this topic. A recurring

theme in this rapidly growing literature—and that of ARI, wheezing, asthma, and COPD—is the heterogeneity of the study populations, the vitamin D regimens used, and the target outcomes. Until these issues are better addressed, it seems likely that we will continue to struggle to understand the exact link between vitamin D and atopy/allergy.

Nevertheless, there is sufficient evidence to suggest that sunlight and/or daily vitamin D supplementation has at least *some* role in preventing allergy, at least among those with vitamin D deficiency and other poorly defined host characteristics. Interestingly, each hypothesized benefit against the atopic/allergic disorders could be explained by vitamin D-mediated effects on innate immunity and the creation of a more salutary microbiome at the different epithelial surfaces—i.e., skin (AD), gut (food allergy), and airway (allergic rhinitis, asthma), with the airway microbiome perhaps altering risk of viral ARI [184]. The 2010 vitamin D-food allergy hypothesis article by Vassallo and Camargo [185] provides a useful example of the complexity that may underlie these different associations. Briefly, we proposed a “multiple hit” model for food allergy in which vitamin D deficiency in a developmentally critical period increases susceptibility to colonization with abnormal intestinal microbial flora and to gastrointestinal infections, contributing to abnormal intestinal barrier permeability and excess and inappropriate exposure of the immune system to dietary allergens. A compounding effect (and additional “hit”) of vitamin D deficiency is the promotion of a pro-sensitization immune imbalance that might compromise immunologic tolerance and contribute to food allergy. Similar models may apply to each of the vitamin D-atopy/allergy outcomes mentioned briefly here. The myriad effects of vitamin D—on lung development, innate immunity, and immunologic tolerance—also are relevant to our understanding of the relation of vitamin D to the different types of ARIs, asthma, and COPD.

## 8. Future research

Although vitamin D has effects on several important respiratory/allergy disorders, many scientific gaps remain. While all study designs can provide helpful information, the field has advanced greatly over the past decade and now needs to focus more on large, well-designed prospective cohort studies and RCTs; there is relatively little value from using a cross-sectional design to demonstrate (again) that people with very low 25(OH)D tend to have worse illness than others with “normal” levels of 25(OH)D. Moreover, future cohort studies and RCTs need to be large enough to explore likely interactions by participant characteristics, and,

for RCTs, by type of vitamin D intervention. While the mainstream media tends to present vitamin D in stark terms—such as amazing, dangerous, or useless—scientists need to avoid these unhelpful simplifications. The more we learn, the clearer it is that there are no easy answers [186]. To that end, I hope that trialists will see the value of the cited IPD meta-analyses on RCTs of vitamin D supplementation and ARI [162,163], asthma exacerbations [132], and AECOPD [175]. This type of international collaboration can help investigators to identify areas of greatest public health potential. Likewise, these collaborations can identify critical areas of uncertainty or topics for which additional studies are unlikely to be helpful.

In that spirit, I suggest below several questions that I think merit further investigation. The ideas are presented using the organizational structure of this chapter; the ordering is not meant to convey anything about their relative importance or feasibility.

## 8.1 Lung development

Are the animal model findings on vitamin D deficiency and lung development (and function) relevant to human lungs? If yes, what is the gestational and postnatal vitamin D status that provides optimal lung health, both in the short-term (with a focus on ARI, wheezing, and asthma) and in the long term (with a focus on incident COPD)?

## 8.2 Acute respiratory infection

- Why is there a strong inverse association between cord blood 25(OH)D and childhood wheezing in some birth cohorts but not in others? Are we missing important effect modifiers?
- Does vitamin D supplementation have different effects on the different microorganisms that underlie the composite outcome of ARI?
- Among individuals with vitamin D deficiency, is daily dosing better than nondaily dosing (including weekly) for preventing ARI?
- Why is bolus dosing ineffective for preventing ARI? Are the beneficial effects of vitamin D supplementation lost or are they offset by some negative feedback loop or new harm? Does a large initial bolus truly negate the observed benefits of daily dosing for preventing ARI?
- What is the target 25(OH)D level for a supplementation regimen that aims to prevent ARI? Is there value in targeting free 25(OH)D or circulating levels of cholecalciferol? (Although this chapter has not addressed these biomarkers, given very limited data on their role in respiratory/allergy disorders, the

detection and assay of vitamin D metabolites are discussed further in [Chapters 48–50](#).

## 8.3 Asthma

### 8.3.1 Asthma pathogenesis

- While most primary prevention studies have focused on prenatal vitamin D supplementation only, does vitamin D supplementation during both pregnancy and early childhood affect the risk of incident asthma?
- Is vitamin D status in adulthood associated with the risk of adult-onset asthma?
- What is the role of genetic factors in the hypothesized link between vitamin D and asthma?

### 8.3.2 Asthma control, including exacerbations

- What are useful biomarkers to identify “responders” to the likely beneficial effect of vitamin D supplementation on corticosteroid effectiveness in asthma?
- What is the effect of vitamin D supplementation on inhaled corticosteroid effectiveness and the prevention of asthma exacerbations in symptomatic children with asthma?
- Most of the questions listed under [Section 9.2](#) of this chapter also apply to asthma exacerbation.

## 8.4 COPD

### 8.4.1 COPD pathogenesis and progression

- Is vitamin D deficiency during pregnancy, early childhood, or adulthood associated with the risk of incident COPD?
- Given the required duration of these longitudinal studies, primary prevention research is likely to benefit from concurrent efforts based on animal models of COPD [187,188].
- What is the role of genetic factors in the hypothesized link between vitamin D and COPD?
- Is vitamin D deficiency associated with faster lung function decline among patients with COPD?

### 8.4.2 AECOPD

- What COPD subgroups, if any, demonstrate an inverse association between vitamin D status and risk of AECOPD?
- If such subgroups exist, what is the effect of daily vitamin D dosing (without initial bolus) on preventing AECOPD? What are the effects of vitamin D supplementation on the noninfectious aspects of AECOPD, such as concurrent heart failure?
- Most of the questions listed under COPD also apply to AECOPD.

## 8.5 Potential mechanisms

### 8.5.1 Immunity

The immunologic effects of vitamin D are a major focus of research and will continue to be so for many years. This research is discussed further in several chapters from [Section 11](#) of this volume. From the perspective of respiratory disorders, the role of vitamin D on innate immunity (e.g., hCAP-18) is of perhaps the greatest interest. If antimicrobial peptides do not mediate the observed reduction in vital ARI, how does vitamin D lower infectious disease risk?

Immunity researchers also are increasingly interested in an earlier and potentially larger question: how does sunlight itself affect immunity and do these effects mediate some of the health benefits that we now attribute to vitamin D? [189]. While basic research is critical for understanding this issue, so are RCTs. For example, when a well-designed and successfully implemented RCT of vitamin D supplementation fails to deliver the expected health benefit, there are many possible explanations, such as enrollment of a nonresponder population or use of a suboptimal vitamin D regimen. However, another explanation is that the value of 25(OH)D levels in the originally reported epidemiological association may have simply reflected its ability to quantify sunlight exposure, which actually was the driving force behind the observation; allocating people to vitamin D and placebo would not change the sunlight exposure that actually was responsible for the desired health effect.

Likewise, when RCTs of vitamin D supplementation are consistent with observational findings, these RCTs confirm, at last at some level, that vitamin D really does contribute to the observed effect. Of course, most associations between vitamin D status and health probably are a mix of phenomena, including both the direct effects of the sun and the direct effects of the vitamin D hormone. For each specific disease (or immunologic outcome), the causal mix could vary—e.g., 20% from sunlight itself versus 80% from vitamin D, or vice versa. The causal mix of sunlight and vitamin D might also vary from person to person, based on individual differences in environment, genes, and lifestyle. While this sunlight versus vitamin D issue may come to a head in terms of immunity research, the lessons learned are likely to apply to many diverse health outcomes.

### 8.5.2 Atopy and allergies

Observational studies report dose-dependent differences in how vitamin D status is associated with atopy/allergy disorders [87–90], which received recent support from a Finnish RCT [190]. Briefly, the authors reported that giving daily vitamin D (400 vs. 1200 IU) from age 2 weeks onward did not provide benefit; on the

contrary, infants randomized to the higher dose had a higher risk of milk allergy and there was increased risk of allergic sensitization among infants with high cord blood vitamin D status. Thus, at least for these atopic disorders, current data appear inconsistent with a simple linear association; simply put, “more is not always better.” For example, it seems likely that both low and high levels of vitamin D during infancy increase the risk of IgE sensitization. This curvilinear pattern would be consistent with how most hormones work, where optimal health requires that the hormone be neither too high, nor too low; instead, the hormone level needs to be somewhere “healthy” between. Although nonlinear associations may also have noncausal explanations, they are a growing focus of vitamin D research. Future studies are likely to demonstrate a relatively broad range of 25(OH)D values that lie in this risk nadir and to show that different diseases have different curvilinear associations. As our indoor lifestyle continues to drive vitamin D status downward, and public enthusiasm for vitamin D supplementation continues to drive 25(OH)D levels higher than are possible with sunlight alone [191], the curvilinear nature of these associations is likely to become increasingly apparent.

The complex association(s) between vitamin D and atopy/allergy are starting to advance an important discussion within the field. Unlike the “traditional” adverse effect monitoring of vitamin D trials in older adults—which focuses on hypercalciuria and hypercalcemia, two rare events until subject reaches extremely high 25(OH)D levels [191]—the observed increases in atopy/allergy risk may start at maternal or infant 25(OH)D levels as low as 40–50 ng/mL. Ongoing studies of vitamin D supplementation during pregnancy and infancy should help researchers to better understand this “new” potential risk, and this, in turn, may affect the use of vitamin D for the prevention and treatment of ARI and other respiratory disorders. The emerging atopy/allergy data encourage a more nuanced decision about vitamin D use and regimen, based not only on individual choices about risk, but on the individual’s environment, genes, and lifestyle. Indeed, recent studies confirm large interindividual variations in serum 25(OH)D response to vitamin D supplementation based on these individual factors [192]. This more nuanced decision-making will help to bring vitamin D supplementation away from the current “one size fits all” approach and into the realm of precision medicine [193].

## 9. Conclusion

Over the past 25 years, many studies have linked vitamin D status with common respiratory disorders, such as childhood wheezing, asthma, and COPD. While

vitamin D probably contributes to human lung development, there is little evidence that vitamin D deficiency affects the risk of developing childhood asthma and sparse data regarding the primary prevention of COPD. By contrast, vitamin D deficiency appears to increase the risk of ARIs, which cause most childhood wheezing and most exacerbations of asthma and COPD. Vitamin D's myriad effects on innate and adaptive immunity provide biological plausibility for how vitamin D deficiency: (1) increases the risk of infection, (2) decreases therapeutic response to corticosteroids; and (3) alters the risk of other related atopic conditions, such as atopic dermatitis, food allergy, and allergic rhinitis.

Further studies, especially well-designed RCTs [158], are needed to clarify the effects of vitamin D supplementation on ARIs and other respiratory disorders, particularly among individuals with vitamin D deficiency. For the primary prevention of asthma and COPD, prospective cohort studies continue to have value—e.g., to identify the characteristics of individuals who are most likely to benefit from a pregnancy or early life intervention with vitamin D. In the case of asthma, future RCTs should expand the vitamin D intervention beyond pregnancy and into early childhood, when children actually start to manifest asthma. The primary prevention of COPD is more complicated given its late onset; longitudinal studies will require decades to reach their primary outcome. Accordingly, primary prevention research may need to focus more on animal models of COPD.

For the prevention of ARI, asthma exacerbation, and AECOPD, I believe that future trials should use a daily supplementation regimen of vitamin D (without bolus) and have sufficient statistical power to determine if vitamin D can prevent (or reduce the severity of) these outcomes, both overall and in major subgroups. Recent IPD meta-analyses [162,163], support ARI prevention in at least subsets of the population. Likewise, the totality of the evidence supports the benefit of vitamin D supplementation in the management of asthma [132] and COPD [175]. However, the optimal person for a vitamin D intervention, and the optimal intervention itself, remain under study. Recent null RCTs remind us that there are no easy answers. At this time, however, I believe the totality of the scientific evidence suggests that correction of vitamin D deficiency is likely to lower the risk of ARI and improve the long-term management of asthma and COPD.

## 10. Summary points

- Vitamin D deficiency has been linked to childhood wheezing, asthma, and COPD.
- This does not appear to be due to effects on lung development but instead may be due to impaired immune responses to ARI.
- Improved supplementation trials are required to confirm a causative role of vitamin D in respiratory disease.

## Vitamin D and acute illness

Karin Amrein<sup>1</sup> and Kenneth B. Christopher<sup>2</sup>

<sup>1</sup>Division of Endocrinology and Diabetology, Medical University of Graz, Graz, Austria <sup>2</sup>Division of Renal Medicine and Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, United States

### OBJECTIVES

- Understand the association between low vitamin D and increased adverse outcomes in the critically ill.
- Identify factors that contribute to low vitamin D status in the critically ill population.
- Appreciate the importance of heterogeneity of critical illness in the interpretation of vitamin D supplementation trials.

### 1. Introduction

Low vitamin D levels are estimated to be present in 30%–50% of the general population [1] and is associated with increased mortality risk [2]. Vitamin D deficiency is observed worldwide and in countries where food fortification of vitamin D and supplemental intake is common. Factors associated with higher risk of low 25-hydroxyvitamin D (25(OH)D) levels include older age, living in the far Northern and Southern hemispheres, low exposure to UVB radiation via sunlight, season, altitude, darker skin pigmentation, and low dietary or supplemental vitamin D intake [3]. Data show that low vitamin D levels are common in the critically ill and are associated with increased mortality and adverse events [4–11].

Patients who are admitted to intensive care units (ICUs) have high mortality. Over the past 30 years, our

care delivery has improved so that previously fatal illness presentations are increasingly survivable. Those ICU patients who survive hospitalization have high risk for mortality and lower quality of life for up to a year after hospital discharge [12,13]. ICU stays are complicated by muscle weakness, critical illness polyneuropathy, and alterations in organ function, which contribute to the reductions in quality of life witnessed in ICU survivors [14]. Powerful data exist showing that ICU survivors have lower health-related quality of life at baseline and at 6 months to 1 year after hospital discharge [13]. As vitamin D receptors (VDRs) and vitamin D metabolic enzymes are distributed widely, vitamin D is an attractive potential modifiable target for critical care outcomes improvement. Indeed, data are emerging relating vitamin D supplementation and critical illness outcomes. The VITdAL-ICU trial [15], a single-center, randomized, double-blind, placebo-controlled trial of 475 critically ill medical and surgical subjects, though negative overall, did show in a secondary outcome that high-dose oral vitamin D<sub>3</sub> significantly improved mortality in patients with severe vitamin D deficiency. The VIOLET trial [16], a multicenter, randomized, double-blind, placebo-controlled phase III trial of 1360 subjects at high risk for ARDS and mortality showed no benefit with high-dose enteral vitamin D<sub>3</sub> supplementation.

This chapter aims to present the current knowledge on vitamin D status in critically ill patients. Vitamin D issues relevant to the critically ill will be highlighted from risk factors to the epigenetics of vitamin D and data from interventional trials.

## 2. Prevalence of vitamin D deficiency in the critically ill patient

With the high level of interest in vitamin D as a potentially modifiable risk factor for critical illness outcome, a number of studies now exist illustrating the epidemiology of serum 25(OH)D levels in the ICU. The potential role of vitamin D in the critically ill has become clearer with a large number of clinical research investigations worldwide. Variability exists in published studies regarding the prevalence of vitamin D deficiency or inadequacy [17]. No universal definition exists for optimal vitamin D status, and existing data highlight comparability problems between 25(OH)D assays [18]. As the serum half-life of 25(OH)D is approximately 3 weeks, total vitamin D status is determined by measurement of 25(OH)D rather than other vitamin D metabolites. Furthermore, 25(OH)D correlates positively with calcium absorption efficiency, unlike circulating levels of active, hormonal 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D) [19].

Consensus statements and experts differ regarding the optimal 25(OH)D level threshold with the Institute of Medicine at 20 ng/mL [20] and the Endocrine Society at 30 ng/mL [21], and most studies will utilize these cut-points. Vitamin D sufficiency can be thought of as a circulating 25(OH)D level that is adequate for physiologic needs. A sufficient 25(OH)D level should maximally suppress circulating parathyroid hormone (PTH), promote calcium absorption, and is associated with the highest bone mineral density. Low 25(OH)D is present in many patient populations worldwide: in young, middle-aged, and elderly adults, particularly in those of African descent [22]. In the United States, most patients have 25(OH)D levels <30 ng/mL [23].

Importantly, 25(OH)D levels deemed sufficient in the population may not be adequate in the critically ill. ICU-based vitamin D studies are not standardized in terms of deficiency cut-points, time of 25(OH)D measurement, or 25(OH)D assay utilized. Abnormal 25(OH)D levels are often variably defined as insufficient, deficient, and severely deficient. A high proportion of critically ill medical and surgical patients have low 25(OH)D levels. Observational data indicate that it is common to find over 50% of ICU cohort patients have 25(OH)D levels that are lower than 30 ng/mL. Studies worldwide report a high prevalence of abnormally low 25(OH)D levels in critically ill patients with different case mixes [4,5,7,9,10]. The prevalence of low 25(OH)D levels in critically ill patients is substantially higher than what is reported in general medical wards [24].

## 3. Vitamin D deficiency risk factors in the critically ill

### 3.1 Ethnicity

Studies in the general population as well as the critically ill demonstrate that dark skin pigmentation is a risk factor for vitamin D deficiency [6]. The synthesis of vitamin D depends on the skin melanin concentration. Individuals with high skin melanin concentration have a less efficient conversion of 7-dehydrocholesterol to previtamin D<sub>3</sub> as melanin absorbs and scatters UV-B. Thus, individuals with dark skin pigmentation have slower vitamin D synthesis than light skin pigmentation (see Chapters 2 and 3). Comparing patients with different skin pigmentation, an association is found between light skin pigmentation and higher 25(OH)D levels. In the critical care environment, patients with dark skin pigmentation have higher proportion of low vitamin D levels relative to those with light skin pigmentation [6]. Vitamin D-binding protein (DBP) allelic combinations are demonstrated to occur at different frequencies in different ethnic groups (see Chapter 7). Despite these differences, there is no difference in the effect of oral vitamin D on serum 25(OH)D levels relative to ethnicity [25–27], an important issue in vitamin D supplementation trials in the ICU.

### 3.2 Seasonality and sun exposure

Most vitamin D synthesis occurs via the skin following UV-B radiation exposure. A single minimal erythema dose exposure (10–12 min of peak summer sun exposure in a light skin pigmentation individual with majority of skin exposed) releases 10,000–20,000 IU vitamin D into the circulation within 24 h [28]. Seasonal variations can be demonstrated in 25(OH)D levels in patients [5,9] (see Chapter 56). Critically ill patients admitted in spring reflect the low sunlight exposure of winter and have lower levels of 25(OH)D and are more often severely deficient (25(OH)D < 15 ng/mL) than in the summer and fall [6,9]. Living at low latitude does not preclude one from low 25(OH)D levels but provides different sunshine periods, more UV-B exposure, and is a potential study design issue regarding the geographic heterogeneity of 25(OH)D levels [29]. Patients at higher altitudes have a more intense UV-B exposure due to the shortened path length of UV-B needs to travel to reach a patient's skin. This results in higher vitamin D production [3].

Sunscreen usage prevents UV-B and partially prevents UV-A radiation from hitting the skin. In studies, sunscreen usage appears to reduce vitamin D synthesis [30] by more than 95% with a sun protection factor (SPF) of 8 and over 98% with an SPF of 15 [31]. Likely from sporadic usage patterns and the general good health of a sunscreen usage population, no study has shown that sunscreens cause vitamin D deficiency. Sunscreen use does not appear to be associated with vitamin D deficiency in the general population [32].

### 3.3 Chronic disease

Chronic disease is associated with alterations in vitamin D status. Conditions that alter intestinal absorption, fat storage, or metabolism by the enzyme 25-hydroxylase can alter vitamin D bioavailability [33]. Kidney production of 1,25(OH)<sub>2</sub>D by the enzyme 25(OH)D-1 $\alpha$ -hydroxylase (1 $\alpha$ -hydroxylase, CYP27B1) is decreased proportionally to the severity of chronic kidney disease mirrored by decreases in circulating 1,25(OH)<sub>2</sub>D [34] (see Chapter 16 and Chapter 79). Patients with higher renal function as measured by creatinine clearance have higher serum 1,25(OH)<sub>2</sub>D levels [35]. With end-stage renal disease 1,25(OH)<sub>2</sub>D may be undetectable depending on residual kidney function. The proteinuria of nephrotic syndrome results in DBP-bound 25(OH)D losses in the urine [36].

Vitamin D<sub>3</sub> is 25-hydroxylated in the liver to produce 25(OH)D. VDR gene polymorphisms may predispose patients to autoimmune liver diseases including primary biliary cirrhosis and autoimmune hepatitis and may be associated with disease severity [37]. Vitamin D deficiency is common with cholestatic liver diseases promoting the European Association for the Study of the Liver to publish guidelines for vitamin D supplementation in this population. Reduction of bile salt availability decreases absorption of the lipophilic vitamin D [38]. Low vitamin D levels are almost universal in patients with chronic liver disease, with a third of patients having 25(OH)D < 12 ng/mL with a higher prevalence in cirrhosis [39] (see Chapter 77).

In published studies, body mass index (BMI)  $\geq$  30 is consistently associated with low 25(OH)D levels. It is postulated that “sequestration” of vitamin D by adipose tissue contributes to the observed low 25(OH)D in patients with BMI  $\geq$  30 [40]. Adipose tissue has the vitamin D receptor and the ability to synthesize 1,25(OH)<sub>2</sub>D. Low 25(OH)D may relate to obesity by the alteration of lipogenesis and/or the regulation of adipose tissue differentiation, mass, and metabolism [41]. BMI is a relatively crude index of adiposity, as it does not quantify

body composition [42]. When serum 25(OH)D values are adjusted for body weight, the difference between patients with BMI  $\geq$  30 and BMI 25–30 is no longer present [43]. Furthermore, it appears that low 25(OH)D may be associated more with markers of glucose homeostasis (insulin resistance, blood glucose) rather than with high BMI [44].

### 3.4 Medication usage

Interactions between medications and vitamin D metabolism and action exist. The pregnane X receptor is a master transcription factor for cytochrome P450 3A4 (CYP3A4), an enzyme important for xenobiotic and drug detoxification. Activation of the pregnane X receptor upregulates 24-hydroxylase (CYP24A1), which increases catabolic degradation of 25(OH)D and 1,25(OH)<sub>2</sub>D, leading to low 25(OH)D levels [45]. Activators of the pregnane X receptor include antiepileptics, antiinflammatory agents, antiretroviral drugs, and the herbal medicines, specifically phenytoin, carbamazepine, cyclophosphamide, taxol, tamoxifen, clotrimazole, rifampicin, dexamethasone, nifedipine, spironolactone, ritonavir, saquinavir, cyproterone acetate, kava, and St. John’s wort [45].

### 3.5 Severity of critical illness and organ failure

ICU patients commonly present with acute-on-chronic organ failure or severe comorbidities, which could relate to the high prevalence of low 25(OH)D observed at ICU admission [6]. This is especially relevant for patients with chronic kidney disease and chronic liver disease as previously noted. Observational studies show a strong link between low 25(OH)D and acute disease severity. Investigators have found that low 25(OH)D is associated with Simplified Acute Physiology Score II (SAPS II) [4], the Sequential Organ Failure Assessment (SOFA) score [4,9,46], Acute Physiology and Chronic Health Evaluation (APACHE) II score [46], and the number of acute organ failures [6]. These findings are not surprising as the level of DBP drops in acute inflammatory conditions common in the critically ill and likely reflects the severity of illness. Partial release of 25(OH)D from the DBP is a likely source of variability for immunoassays commonly used to determine 25(OH)D. Patients with inflammation and sepsis have lower DBP concentrations, which may factor in the low 25(OH)D levels observed in ICU patients when measured with LC-MS/MS [47].

#### 4. Vitamin D mechanisms in critical illness

Vitamin D status affects a large number of biological processes vital to the critical illness response, including gene expression, protein synthesis, metabolism, signal transduction, and cellular proliferation. The mechanism of action of vitamin D involves  $1,25(\text{OH})_2\text{D}$ , VDR and its associated transcriptional coactivators, plasma transport by DBP, the vitamin D-activating cytochrome P450s (CYP27A1, CYP27B1 and CYP2R1), and the vitamin D-catabolic cytochrome P450 CYP24A1 (see Chapters 4–13). A photosynthetic mechanism in human skin via UV-B radiation converts 7-dehydrocholesterol to previtamin  $\text{D}_3$ , and then to vitamin  $\text{D}_3$  via thermally induced isomerization. Vitamin  $\text{D}_3$  is subsequently hydroxylated to  $25(\text{OH})\text{D}$  in the liver and again in the kidney to form biologically active  $1,25(\text{OH})_2\text{D}$ . When vitamin D enters the circulation after UV-B generation, it is coupled primarily with DBP. In contrast, after intestinal absorption, vitamin D enters the circulation and is coupled with both DBP and lipoproteins [48]. Additionally, autocrine production of  $25(\text{OH})\text{D}$  exists in tissues containing the vitamin D 25-hydroxylase [49]. Activation of human monocytes or macrophages by ligands of Toll-like receptors, IFN- $\gamma$  or CD40 ligand, results in upregulation of  $1\alpha$ -hydroxylase and nuclear VDR expression and increased conversion of  $25(\text{OH})\text{D}$  to  $1,25(\text{OH})_2\text{D}$  [50]. Vitamin D, produced in the skin or from intestinal uptake, is delivered primarily to the liver, hydroxylated to  $25(\text{OH})\text{D}$ , which is then associated with DBP and then released to the circulation [51].

The main serum carrier of  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$  is DBP, while albumin can act as a low-affinity binder [52]. The pharmacokinetics and distribution of vitamin D metabolites are determined by lipophilicity and the relative activities of vitamin D synthetic and catabolic enzymes [53].  $1,25(\text{OH})_2\text{D}$  is a powerful inducer of CYP24A1 expression and 24-hydroxylase activity and  $24,25(\text{OH})_2\text{D}$  formation, a metabolite of  $25(\text{OH})\text{D}$  of unclear function [54], although 24-hydroxylase can also catabolize  $1,25(\text{OH})_2\text{D}_3$  [55].

Inflammation is associated with decreased levels of DBP [56,57]. Additionally, DBP levels fall with severe tissue and cell damage. The extent of DBP reduction is associated with the acuity of illness with low DBP levels noted in critically ill patients with acute organ dysfunction, respiratory failure, hematologic failure, sepsis, and ARDS [58]. Importantly for the critically ill, DBP also has activity in actin scavenging, macrophage activation, and fatty acid transport [59]. With apoptosis, cell death and tissue injury actin are released systemically into the circulation. Outside of the cell, G-actin polymerizes into F-actin filaments, which may contribute to multiple

organ dysfunction syndrome. DBP binds to G-actin monomers accentuating G-actin clearance via the liver [60].

The phosphaturic hormone FGF23 is produced by osteocytes that plays an important role in vitamin D homeostasis [61] (see Chapter 19). FGF23 is a  $1\alpha$ -hydroxylase inhibitor and a 24-hydroxylase stimulator resulting in decreased activation of  $25(\text{OH})\text{D}$  and increased  $25(\text{OH})\text{D}$  and  $1,25(\text{OH})_2\text{D}$  catabolism [62]. FGF23 induces expression of CYP24A1 [62] at the same time that elevated PTH inhibits kidney expression of CYP24A1 [63]. In critically ill patients, the interplay between  $25(\text{OH})\text{D}$ ,  $1,25(\text{OH})_2\text{D}$ ,  $24,25(\text{OH})_2\text{D}$ , FGF23, and PTH is not well described.

VDR [64,65] and vitamin D metabolic enzymes [66,67] are present in tissues other than bone and the intestine, indicating that vitamin D is involved in the metabolism and function of many cell types. In particular, VDRs are expressed in T cells, activated B cells, neutrophils, and dendritic cells [68,69] (see Chapters 94–96). Vitamin D deficiency experimental studies have demonstrated defects in macrophage chemotaxis, phagocytosis, and the production of proinflammatory cytokines [70]. Vitamin D also links Toll-like receptor (TLR) activation and innate immunity [71] (see Chapter 94). Human macrophage stimulation by TLR induces  $25(\text{OH})\text{D}$  conversion to  $1,25(\text{OH})_2\text{D}$  as well as VDR expression and antimicrobial peptide production (see Chapter 9). Furthermore,  $1,25(\text{OH})_2\text{D}$  is important in upregulating genes essential for tight junctions, gap junctions, and adherens junctions, which promote barrier integrity [72].

The transcription of multiple inflammatory cytokines is influenced by  $1,25(\text{OH})_2\text{D}$  [73]. Human monocytes incubated with  $1,25(\text{OH})_2\text{D}$  have downregulated pathogen receptor molecules and inflammatory responses following exposure with *Candida albicans*, bacterial ligands, lipopolysaccharide (LPS), and lipoteichoic acid [74]. During human macrophage differentiation, differential expression of VDR and  $1\alpha$ -hydroxylase exist suggesting that vitamin D may encourage the differentiation of precursor monocytes to mature phagocytic macrophages [75].  $1,25(\text{OH})_2\text{D}_3$  is related to the oxidative burst potential via activation of human monocyte secretion of hydrogen peroxide [76] (see Chapter 9).

Vitamin D may modulate the immune response to sepsis via regulation through CYP24A1 and TLR. Activity of 24-hydroxylase, the catabolic enzyme of vitamin D, which attenuates responses to  $1,25(\text{OH})_2\text{D}$ , is functionally altered by splicing variants of CYP24A1 [77].  $1,25(\text{OH})_2\text{D}$  also downregulates monocyte TLR2 and TLR4 expression, which may blunt the inflammatory response to TLR ligands providing a potential negative feedback regulation [78].

Data indicate that vitamin D also influences adaptive immunity through differentiation of inflammatory T helper 17 (Th17) T cell subsets and regulatory T cells (Treg cells) [79]. Via production of IL-17, Th17 cells accentuate inflammation and chemotaxis of neutrophils. Data show that Th17 cells can transdifferentiate into Treg cells, which are important for inflammation resolution and the beginnings of organ repair in critical illness [80]. Additional evidence lends credence to the hypothesis that Treg cells are central to inflammation resolution in animal models of acute lung injury [81]. Importantly, 1,25(OH)<sub>2</sub>D regulates expression of FOXP3 in CD4<sup>+</sup> T cells important for the development and functioning of Treg cells [82] (see Chapter 96).

Vitamin D exerts stimulatory effects on innate immunity and can also suppress hyperreactive immune response [71]. Biologic evidence shows that vitamin D promotes Treg cell induction, T helper 1 and 2 (Th1 and Th2) response modulation, Th17 cell suppression, and the regulation of dendritic cell maturation [79]. In a rodent model of sepsis, pretreatment with vitamin D showed lower decrements in platelet counts, while another shows improved short-term survival rates [83,84]. In other experimental models of sepsis, 1,25(OH)<sub>2</sub>D administration was associated with improved blood coagulation parameters in sepsis-associated disseminated intravascular coagulation [85]. Experimental meningoencephalitis caused by *Escherichia coli* was associated with worse outcomes in animals with low vitamin D [86]. In experimental peritonitis, vitamin D deficiency significantly increased systemic, local, and bronchoalveolar lavage quantitative bacterial culture [87]. VDR null mice have heightened mortality following LPS-induced endotoxemia [88]. Human endothelial cells exposed to 1,25(OH)<sub>2</sub>D have an attenuated inflammatory response following LPS administration [89].

## 4.1 Antimicrobial peptides

An important role of vitamin D is the upregulation of antimicrobial peptide (AMP) production in response to various pathogens via the innate immune system [90]. AMP production occurs within minutes of pathogen recognition. Human AMPs include cathelicidin, 6  $\alpha$ -defensins, and 4  $\beta$ -defensins. Specifically, vitamin D upregulates cathelicidin and  $\beta$ -defensins with broad-spectrum antimicrobial effects expressed in plasma as well as barrier tissues such as airway, bladder, and gastrointestinal epithelium [91] (see Chapter 94).

### 4.1.1 $\beta$ -2

The expression of  $\beta$ -defensin 2 occurs in airway epithelial cells and keratinocytes with induction

following inflammatory signals. 1,25(OH)<sub>2</sub>D induces genes that encode  $\beta$ -defensin 2 [92].  $\beta$ -2 activates innate immunity via activity in phagosomes or phagolysosomes [93].  $\beta$ -2 increases host resistance to gram-negative bacteria and *Candida albicans* [94]. In addition,  $\beta$ -defensin 2 increases host resistance to respiratory syncytial virus, influenza A virus, para influenza virus, and adenovirus [95]. Further,  $\beta$ -defensin 2 is increased in the GI epithelium as a barrier response to potential pathogens [96].

### 4.1.2 Cathelicidin

Cathelicidin is produced by cells that are in contact with the environment (mucosal epithelium, keratinocytes) and cells of the innate immune system [97]. VDR activation is important for cathelicidin production as a vitamin D response element (VDRE) sequence is present in the promoter region of the cathelicidin gene [98]. Cathelicidin regulates inflammatory responses, accentuates chemotaxis, promotes phagocytosis, increases vascular permeability, improves wound healing, and promotes the production of reactive oxygen species, the disruption of bacterial biofilm, and the neutralization of lipopolysaccharides [91,99]. Cathelicidin also is noted to increase cell stiffness and decrease cell permeability in the lung epithelium resulting in decreased cell infection [100]. Cathelicidin can recruit and induce proliferation of endothelial progenitor cells to wound sites during healing. Importantly, cathelicidin regulates apoptosis of epithelial cells and neutrophils extending the time of chemokines and cytokines production and microbe clearance [101]. Further, it is demonstrated that cathelicidin binds to self-DNA a potent activator of innate immunity [102]. Cathelicidin is rapidly upregulated in urinary epithelial cells in response to infection [103] and in skin epithelial cells quickly following wounding [104]. The activated form of cathelicidin, LL-37, has direct microbicidal effects on vancomycin-resistant enterococci, *Pseudomonas aeruginosa*, *Salmonella typhimurium*, *Escherichia coli*, *Listeria monocytogenes*, *Staphylococcus aureus*, and *Staphylococcus epidermidis* [105]. LL-37 kills bacteria by membrane permeation and disruption by the helical region [106]. In vitro, LL-37 binds *Escherichia coli* LPS, which suggests that LL-37 may serve to neutralize low levels of circulating LPS [105].

Experimentally, the effect on pathogens by vitamin D varies. In vivo, CD14<sup>+</sup> cells increase 1 $\alpha$ -hydroxylase expression following infection [107]. In a study of postmenopausal women supplemented with 2000 units of daily oral 25(OH)D<sub>3</sub> for 12 weeks, bladder biopsy tissue obtained at week 0 and week 12 showed a significant increase in cathelicidin expression over time with experimental infection with uropathogenic *E. coli* [108]. In a study on human airway epithelial cells, cathelicidin

production was induced by vitamin D with enhanced capacity to kill *Pseudomonas aeruginosa* and *Bordetella bronchiseptica* [109]. The antimicrobial effect is not universal. In vivo experiments show that LL-37 is not induced in human monocytes following salmonella bacterial infection and clearance [110]. In experimental colitis, 1,25(OH)<sub>2</sub>D pretreatment increased susceptibility to *Citrobacter* via mucosal Th17 responses suppression [111]. Further, experimental group A streptococcal exposure to low-dose LL-37 caused resistance to killing by human neutrophils [112].

While the evidence for the role of cathelicidin in innate immunity is strong, it is not certain if plasma LL-37 is a marker of the effect of vitamin D. In study volunteers, a positive correlation exists between serum 25(OH)D and free LL-37 levels when serum 25(OH)D concentrations < 32 ng/mL [113,114]. A vitamin D supplementation study in healthy volunteers showed the greatest increase in free LL-37 levels occurred in subjects with the highest increase in 25(OH)D [113]. In the ICU patient population, a significant positive correlation exists between 25(OH)D serum levels and cathelicidin production [56]. In a study of 112 hospitalized patients with community-acquired pneumonia, cathelicidin levels were not associated with 25(OH)D [115]. In the dialysis population, associations exist between cathelicidin and infectious disease outcome [116]. In the ICU patient population, a significant positive correlation exists between 25(OH)D serum levels and cathelicidin production as well as associations between low cathelicidin and increased mortality [56,117].

#### 4.1.3 Inflammasome activation

In critically ill patients, pathogen-associated molecular patterns or host cell–derived damage-associated molecular patterns such as circulating mitochondrial DNA [118] and fatty acid synthase–dependent lipid synthesis trigger Toll-like receptors to initiate transcriptional priming of the NLRP3 inflammasome [119]. The NLRP3 inflammasome is a multiprotein complex that promotes caspase-1 activation and cleavage of pro-IL-1 $\beta$  and pro-IL-18 to intensify inflammation [120]. Vitamin D may be important for NALP3 inflammasome regulation [121] and autophagy [92]. Human-derived peripheral blood mononuclear cell (PBMC) studies related to vitamin D regulation of TLR-2, TLR-4, GATA-3, VDR, pp38, ERK1/2, and p65 are supportive of an antiinflammatory effect of vitamin D [74,122]. By extension, it is possible that vitamin D supplementation in critical illness blunts inflammasome activation via preservation of mitochondrial integrity based on structural studies that show mitochondrial alterations and lower mitochondrial number in sepsis nonsurvival [123].

Bacterial toxins, pathogen-associated molecular patterns, and reactive oxygen species (ROS) trigger the association of the NALP3 inflammasome with thioredoxin-interacting protein (TXNIP) in human macrophages, which may be regulated by vitamin D [121]. Recent in vitro experiments suggest that vitamin D<sub>2</sub> analog treatment may depress TXNIP mRNA and protein expressions [124]. Additionally, thioredoxin (TRX) is important for redox regulation, interacts with TXNIP, and is downregulated by vitamin D<sub>3</sub> [125]. It is further observed that vitamin D can upregulate NOD2 [92], an NLR protein in the same family as the inflammasome NALP3. Studies have linked NOD2 function to autophagy [126,127], and autophagy proteins regulate innate immunity via inhibition of mitochondrial DNA (mtDNA) release via by the NALP3 inflammasome [128]. Mitochondrial dysfunction and an impaired autophagic response are reported to be associated with worsened mortality from murine sepsis [128]. Recently, in two critical ill cohorts, it was shown that elevated circulating mtDNA levels are a robust predictor of increased 28-day mortality in medical ICU patients [129].

Autophagy is a lysosome-mediated catabolic pathway and core cellular housekeeping processes to ensure synthesis, degradation and recycling of macromolecules, and inclusions in mononuclear cells [130]. Autophagy is an inducible response to stress triggered by hypoxia, hyperoxia, pharmaceuticals, oxidative stress, proinflammatory states, and endoplasmic reticulum stress [131]. Autophagy also regulates innate immune responses [128]. Vitamin D signaling appears to regulate autophagy at different steps, including induction, nucleation, elongation to maturation, and degradation. Cathelicidin induces autophagy activation and autophagolysosome formation in human monocytes/macrophages [130]. Additionally, vitamin D signaling regulates autophagy to decrease autophagy-related damage and to decrease invasion of microorganisms [132].

#### 4.2 Metabolomics, transcriptomics, and epigenetics of vitamin D

In critical illness, severe disruption of many metabolic pathways occurs with loss of metabolic homeostasis [133]. Analyzing metabolites at a particular time point gives a picture of the functional product of the relationship between genes, transcription, proteins, and environmental factors [134]. Critical illness severely disrupts homeostasis affecting a large number of metabolic pathways [133]. In the critically ill, metabolic profiles are the end product of the response at the cellular level to injury, inflammation, infection, hypoxia, oxidative stress, and micronutrient depletion [135]. However,

the metabolic consequence of low vitamin D status in the critically ill is not known. Vitamin D has extensive influence on apoptosis, nuclear transcription as well as cell cycle regulation and differentiation [136]. The tissue distribution of vitamin D receptors and vitamin D metabolic enzymes is broad and underscores the importance of vitamin D in the function and metabolism of numerous cell types [137]. Vitamin D deficiency alters biological processes that are important for the immune response such as gene expression, cytokine production, cellular function, and metabolism.

Evidence supports different metabolomic profiles in ambulatory patients who respond to vitamin D supplementation compared with those who respond poorly [138,139]. Studies are emerging that consider the influence of vitamin D on the critical illness metabolome [140–142]. Significant differences exist in the metabolome relative to vitamin D status early in critical illness [140]. With high-dose vitamin D<sub>3</sub> intervention, patterns of metabolite change during early critical illness differ according to the 25(OH)D level response [141]. Furthermore, women have significantly different pharmacokinetics and metabolic responses to high-dose vitamin D<sub>3</sub> intervention compared with men [142].

Gene expression during critical illness is regulated by epigenetic mechanisms, which modify inflammatory responses and host defense (see Chapter 12 and Chapter 14). The epigenetic effect of vitamin D is primarily covalent modification of histones by acetylation [143]. Vitamin D mediates an epigenetic effect via binding with the VDR. Vitamin D both regulates epigenetic events and also is itself regulated by epigenetic means. The vitamin D signaling system genes coding for the enzymes 25-hydroxylase, 1 $\alpha$ -hydroxylase, 24-hydroxylase, and the VDR can be silenced by DNA methylation due to the CpG islands located in the promoter regions [144]. VDR protein physically interacts with coactivator and corepressor proteins. This is then followed by interaction with chromatin modifiers (histone acyltransferases, histone deacetylases, histone methyltransferases) as well as with chromatin remodelers (histone demethylases of the Jumonji C-domain containing proteins, and lysine-specific demethylase families) [145].

Low 25(OH)D in some patients has been found to be related to specific genetic variants [146]. Single-nucleotide polymorphisms (SNPs) in vitamin D activation or degradation enzymes as well as in the DBP can alter serum 25(OH)D concentrations and metabolites [146,147] (see Chapter 60). The vitamin D<sub>3</sub> supplementation response as measured by 25(OH)D levels is dependent upon baseline vitamin D status and high body mass index [148]. A genetic basis for vitamin D supplementation response may contribute to the large variability noted in 25(OH)D levels following equal vitamin D supplementation doses [149].

Genetic factors have a large influence on critical illness, specifically regulation of genes involved in immune response regulation. Susceptibility to and outcome of critical illness may be related to polymorphisms of genes involved in the expression of inflammatory cytokines, innate immunity pathways, and the coagulation cascade. The following polymorphisms may be significant for sepsis vulnerability and critical care outcomes: bacterial permeability increasing protein, CD14, IgG receptors, IL-10, IL-6, lipopolysaccharide binding protein, lymphotoxin alpha, macrophage migration inhibitory factor, mannose-binding lectin, plasminogen activator inhibitor-1, TLRs, and tumor necrosis factor may be important in sepsis susceptibility and outcomes [150].

Vitamin D regulates over 1000 genes, and genetic differences may contribute (albeit as a small percentage) to the wide variation found in serum 25(OH)D levels (see Chapter 60). DBP and VDR SNPs are noted to correspond to alterations in vitamin D metabolism and altered immune response to infections [151,152]. SNPs at restriction enzyme sites D432E and T436K are known to change the VDBP protein structure. This altered structure is found in the common Gc1f, Gc1s, and Gc2 variants of VDBP, which alter the VDBP to 25(OH)D-binding affinity and bioavailability and subsequently modify LL-37 induction [151,152]. In the VDR, SNPs at restriction endonuclease sites for Taq1, Bsm1, and Fok1 restriction enzyme sites are associated with infectious disease [153]. The Fok1 SNP in the VDR gene affects VDR signaling in immune cells resulting in dampening of the cytokine response to inflammation [154].

## 5. Vitamin D and critical care patients

### 5.1 Assays for vitamin D

Circulating 25(OH)D is difficult to measure as it is highly hydrophobic, strongly bound to DBP (dissociation constant,  $K_d$ ,  $5 \times 10^{-8}$  M); there is negligible non-protein-bound 25(OH)D in blood, and few of the available DBP-binding sites are bound to 25(OH)D. Comparing clinical studies that measure 25(OH)D in the ICU has limitations due to the differences in the assays to measure 25(OH)D. 25(OH)D assays utilize (1) extraction with organic solvents, reconstitution in a matrix, and then quantification via immunoassay or (2) separation via chromatography. The organic solvents that are necessary to separate DBP from 25(OH)D are not compatible with most protein-binding assays or immunoassays. The measurement of 25(OH)D is indirectly measured by competitive binding methods via protein-binding assays and immunoassays and directly

measured by chromatographic separation by liquid chromatography–tandem mass spectroscopy (LC-MS/MS) and high-performance liquid chromatography (HPLC) (see Chapter 48). Method comparison studies of various 25(OH)D assays show variability between methods [18,47] (see Chapter 49), and DBP concentration-dependent inaccuracies occur with 25(OH)D immunoassays [47]. Critically ill septic patients and those with inflammation or organ dysfunction have low DBP concentrations. Biologically active 25(OH)D is dependent on the 25(OH)D concentration and the protein isoform of DBP. These issues may be responsible for the low 25(OH)D concentration observed when measured with LC-MS/MS in critically ill patients [47,56].

Variation occurs in analysis of 25(OH)D levels due to reagent standardization, operator expertise but most importantly assay type. Standards for 25(OH)D assay type employed or cut-points for specific 25(OH)D assay used do not exist. Work performed toward standardization of 25(OH)D assays include the Vitamin D External Quality Assessment Scheme, US National Institute for Standards and Technology, and the University of Ghent. Due to assay variation, cut-points for determining “deficiency” will need to be assay specific. Due to assay variation and nonstandardization, it is important to take into consideration assay type when comparing clinical studies, interpretation of metaanalyses, and policy discussions regarding cutoffs for deficiency and supplementation of 25(OH)D. Please refer to Chapter 49 for a more detailed discussion of this topic.

## 5.2 Observational data

Mortality risk in the general population drops with increasing 25(OH)D levels, with the most favorable levels at 30–35 ng/mL. Vitamin D supplementation is associated with a small decrease in all-cause mortality [155]. High levels of 25(OH)D (>40 ng/mL) may be required for peak immune function [156]. A large meta-analysis on adult outpatients demonstrated that low 25(OH)D was associated with increases in all cause-mortality [157]. Mendelian randomization studies indicate that vitamin D deficiency increases mortality but only at very low levels of 25(OH)D [158,159]. In hospitalized patients, there is a relationship between vitamin D levels and important outcomes. Serum 25(OH)D concentrations <20 ng/mL in hospitalized adults are associated with unfavorable outcomes including heightened mortality [160]. Genetic differences in the vitamin D receptor may account for the vitamin D–clinical outcomes relationship [161].

### 5.2.1 Vitamin D and critical illness outcomes

A low vitamin D level in the critically ill (serum 25(OH)D ( $\leq 20$  ng/mL) is common being present in up to 50% of patients [4–11]. Low vitamin D levels in the critically ill are associated with increased infection severity and increase cost [5,162]. Low serum 25(OH)D appears to be a biomarker of severity of illness and critical illness outcomes and raises the possibility of vitamin D as a modifiable risk factor through supplementation [4–11]. It is postulated that low vitamin D levels may play a role in adverse critical illness outcomes, including metabolic derangement, infection, development, and outcome of sepsis and multiorgan failure [17,163,164]. Studies show an inverse relationship between vitamin D and severity of illness [4,9]. Critically ill patients with low vitamin D levels have an increase in all-cause mortality [4–11]. In ICU survivors, low vitamin D levels is related to higher likelihood of facility placement following hospital discharge [165].

### 5.2.2 Sepsis

Sepsis is a common cause of death worldwide and the most common cause of death among critically ill patients outside of coronary ICUs [166]. The yearly cost of care for hospitalized patients with sepsis is \$20 billion in the United States [167]. Observational data suggest that low vitamin D levels may contribute to sepsis development and sepsis outcomes primarily due to alteration in the innate immune responses [163].

Data from critically ill patients indicate that patients with low vitamin D (25(OH)D  $\leq 15$  ng/mL) have a higher risk for mortality, bloodstream infection, and sepsis [4–8,162,163]. In addition, low vitamin D levels in the critically ill are a strong predictor for organ dysfunction [5–7,163]. Low vitamin D prior to hospital admission is associated with sepsis susceptibility and increased mortality in septic patients [163]. Metaanalyses of 14 observational studies in the critically ill demonstrated that low vitamin D increases susceptibility for severe infection susceptibility and mortality [168].

### 5.2.3 Acute Kidney Injury

Critically ill patients with preexisting low vitamin D levels (25(OH)D  $\leq 15$  ng/mL) have higher risk of development of acute kidney injury (AKI) [7]. Experimental models of renal ischemia reperfusion (IRI) show that low vitamin D levels accentuate AKI [169]. In particular, rats with low vitamin D have a more pronounced drop in glomerular filtration rate, higher urinary protein excretion, attenuated renal aquaporin 2 expression, and more substantial histological damage (specifically tubular necrosis) following IRI [169]. Experimental IRI in the context of low vitamin D shows increased

inflammation and fibrosis, lower renal repair responses, and more pronounced changes in renal capillary density [170].

Vitamin D supplementation prior to experimental LPS-induced AKI results in attenuation of the renal inflammatory response, pathological damage, and serum creatinine [171,172]. The mechanism for potential nephroprotection with vitamin D could be through NF- $\kappa$ B and the renin–angiotensin–aldosterone system (RAS). NF- $\kappa$ B family transcription factors mediate the immune response through regulation of inflammation and fibrosis gene expression including TNF- $\alpha$ , MCP-1, PAI-1, and additional proinflammatory mediators [173]. Renal MCP-1 enhances macrophage infiltration, which releases mediators that increase renal injury severity [174]. In experimental AKI, NF- $\kappa$ B is noted to be activated in the renal tubular cells [175]. In renal transplant patients with delayed graft function due to AKI, NF- $\kappa$ B activation can be demonstrated in kidney biopsy tissue [176]. 1,25(OH) $_2$ D downregulation of the expression of genes for IL-12, IL-8, MCP-1, PAI-1, angiotensinogen, and microRNA-155 by blocking NF- $\kappa$ B activation via VDR physical interaction with IKK $\beta$  [177]. VDR-deficient fibroblasts have constitutional activation of NF- $\kappa$ B [178]. In an experimental model, paricalcitol, a vitamin D analog, which binds VDR, reduces kidney-related inflammation by NF- $\kappa$ B activity blockade [179]. In vitro, endothelial cells derived from human coronary arteries, proinflammatory cytokine production is blunted by 1,25(OH) $_2$ D through interference of the TNF- $\alpha$ -induced activation of NF- $\kappa$ B [180]. In experimental AKI, expression of NF- $\kappa$ B was attenuated with paricalcitol pretreatment [181].

Angiotensin II is well known as a vasoconstrictor that also acts as an inducer of cell proliferation, inflammation, oxidative stress, and fibrogenesis. Angiotensin II-induced reactive oxygen species may have an important role in AKI. During kidney injury, angiotensin II induces profibrotic, proinflammatory cytokines, and growth factors [182]. Angiotensin II is also related to enhancement of immune cell infiltration, extracellular matrix synthesis, podocyte damage, cell hypertrophy, and cell proliferation [182]. Evidence suggests that 1,25(OH) $_2$ D inhibits gene transcription of renin through the cAMP-signaling pathway [183].

#### 5.2.4 Acute lung injury

In community-dwelling patients, self-reported respiratory infection is lower in patients with high 25(OH)D [184]. In outpatients, pneumonia development is noted to be lessened with higher vitamin D levels [185]. Study of hospitalized patients with pneumonia shows that low 25(OH)D levels are associated with heightened mortality and improve the performance of a pneumonia severity index score [186]. Critically ill patients with

preexisting low vitamin D levels have higher risk of development of acute lung (ALI) and a higher mortality if ALI develops [187].

Vitamin D is a robust stimulator of antimicrobial peptides in the lung. 1,25(OH) $_2$ D has the ability to induce the release of the potent proinflammatory protein LL-37 within the lung bronchial epithelium [109]. LL-37 is stored at high concentrations in neutrophil secondary granules in the inactive proform hCAP18. LL-37 is present in airway secretions and induced in response to inflammation and infection [188]. High concentrations of LL-37 are found in bronchial alveolar lavage fluid from ARDS subjects compared with control subjects [189].

In vitro, conversion of 25(OH)D to 1,25(OH) $_2$ D is observed in respiratory epithelial cells [190]. Exposure of respiratory epithelial cells to 25(OH)D results in upregulation of LL-37 and CD14 [190]. 1,25(OH) $_2$ D is reported to decrease the activation level of lung microvascular endothelial cells, with reduction of ICAM-1, ELAM-1, iNOS, and PAF-related neutrophil adhesion [191].

Evidence suggests that in addition to the AMP effects, LL-37 may be involved in epithelial repair in ALI [192]. Further, in vivo experiments with human neutrophils show increased local LL-37 in response to vitamin D increases phagocytosis of bacteria and decreases TLR agonist-mediated increases in TNF- $\alpha$ , IL-1 $\beta$ , IL-6, and IL-8 [193].

Experimental models in ALI and vitamin D supplementation are not consistent. In a hamster model of ALI, 1,25(OH) $_2$ D inhibits neutrophil recruitment by 40%, postulated to be related to inhibition of IL-8 [194]. In a rat model of ALI associated with ischemia reperfusion of bilateral femoral arteries, 1,25(OH) $_2$ D pretreatment blunts observed lung injury [195]. In a rodent model, 1,25(OH) $_2$ D pretreatment is shown to attenuate seawater aspiration-induced ALI, thought to be due to NF- $\kappa$ B and RhoA/Rho kinase pathway inhibition [196]. In a rodent model of LPS-induced ALI, the absence of VDR was associated with more severe ALI, while vitamin D pretreatment attenuated LPS-induced lung injury with preservation of alveolar barrier function [197]. Others have found no difference in the severity of LPS-induced ALI with regard to vitamin D deficiency [198].

### 5.3 Interventional data

Vitamin D treatment to achieve a sufficiency target (e.g., 25(OH)D > 20 ng/mL) [20] has not yet been established to improve patient outcomes [199]. Vitamin D intervention is an attractive therapeutic target in the critically ill as it is inexpensive, has substantial biological

evidence of efficacy, and appears safe in trials of ICU patients [15,200,201]. Outside the ICU, some interventional trials show an antiinflammatory and immunomodulatory role of vitamin D [202,203]. Some studies on vitamin D supplementation show improvement related to bacterial [203,204] and viral infection outcomes [205]. A systematic review and metaanalysis of 43 RCTs suggests vitamin D supplementation in those with low 25OHD < 12 ng/mL may reduce respiratory infections [206].

It is important to underscore that vitamin D supplementation studies do not consistently show benefit [207–211]. Single high-dose annual vitamin D supplementation in older women was shown to increase fall and fracture risk [212]. In hospitalized children with pneumonia, two vitamin supplementation D trials failed to show decreased illness duration, but one had a lower pneumonia recurrence rate [213,214]. Another vitamin supplementation D trial did not demonstrate differences in pneumonia incidence in infants [215]. Vitamin D supplementation trials in adults have failed to demonstrate differences in respiratory infections [207,216,217]. In a high-dose vitamin D interventional trial on outpatients with COPD, the time to first exacerbation outcome was not significantly different [209]. A post hoc analysis in trial patients with very low baseline vitamin D levels showed that COPD exacerbations were less in the intervention arm suggesting that intervention may need to be targeted to a particular 25(OH)D level [209]. When interpreting vitamin D supplementation trials, it is important to take into consideration the design issues including population studied, baseline 25(OH)D status, DBP levels, sufficient study power, dose given and in what setting, supplementation type (vitamin D<sub>2</sub> vs. D<sub>3</sub> vs. calcitriol), duration of supplementation, severity of illness, case mix, primary outcome, and the event rate of primary outcome.

The Correction of Vitamin D Deficiency in Critically Ill Patients (VITdAL-ICU trial) was a randomized, double-blind, placebo-controlled, single-center trial of 475 ICU patients with 25(OH)D ≤ 20 ng/mL randomized 1:1 with 540,000 IU oral cholecalciferol followed by monthly maintenance doses of 90,000 IU for 5 months versus placebo [15]. The primary outcome was hospital length of stay. By the design, investigators only included patients with low vitamin D levels. The results show that there was not a significant difference for the primary outcome length of stay. In the secondary outcome of mortality, there were nonsignificant differences in survival.

The VITdAL-ICU trial showed a survival benefit in subjects with very low vitamin D (25(OH)D ≤ 12 ng/mL) who were randomized to the vitamin D group [15]. In trial subjects with very low vitamin D (N = 200; 42% of the study population), hazard ratios for mortality among the vitamin D group, as compared

with the placebo group, were as follows: in-hospital mortality HR = 0.56 (95% CI, 0.35–0.90; *P* = .01); 28-day mortality HR = 0.52 (95% CI, 0.30–0.89; *P* = .02), and 6-month mortality HR = 0.60 (95% CI, 0.39–0.93; *P* = .02). In trial subjects with very low vitamin D, the absolute risk reduction was 15.9% for 28-day mortality and the number needed to treat was 6. This interventional study is supportive but not definitive of the hypothesis that vitamin D supplementation targeted to critically ill patients with very low vitamin D [25(OH)D ≤ 12 ng/mL] may improve outcomes [15]. While the study is considered a neutral trial, there is still much progress to be made, the balance of evidence supports vitamin D<sub>3</sub> supplementation as a promising intervention in patients with severe vitamin D deficiency, which merits further investigation.

Though the VITdAL-ICU trial is intriguing, the mortality difference data must be viewed as hypothesis generating as it was not the primary outcome, and the trial was not powered to mortality. The results of the VITdAL-ICU trial should not be used to guide therapy but are helpful in deciding how to design the next large trial on vitamin D supplementation. Paramount issues for trial design in vitamin D are the understanding that for vitamin D supplementation to work, investigators must identify the population that may benefit. The VITdAL-ICU trial may assist investigators with issues regarding sample size, drug, dose, duration, and identification of a subgroup (i.e., 25(OH)D ≤ 12 ng/mL) that may benefit most from supplementation. Further trials are warranted based on the strength of the biological data, the observational data, and the limited interventional data in critically ill patients. If replicated in a multicenter randomized controlled trial, the VITdAL-ICU trial data indicate that the most fruitful time to intervene is early during an ICU course, an appropriate dose of oral cholecalciferol is in the high range, and the subjects who are most likely to benefit are those with low 25(OH)D at the time of enrollment.

The Cholecalciferol Supplementation for Sepsis in the ICU study was a randomized controlled trial of 30 critically ill patients with new-onset severe sepsis or septic shock randomized 1:1:1 to placebo versus 200,000 IU cholecalciferol versus 400,000 IU cholecalciferol [218]. The primary trial goal was to evaluate the change in circulating 25(OH)D levels, bioavailable 25OHD (determined from 25(OH)D, DBP, and albumin levels), and LL-37 expression. Investigators reported that the 400,000 IU cholecalciferol dose significantly and rapidly increased circulating 25(OH)D levels, bioavailable 25(OH)D, and expression of LL-37. Additionally, it was shown that the 400,000 IU cholecalciferol dose significantly reduced systemic levels of IL-1β and IL-6 [218].

Leaf et al. performed a novel randomized controlled trial of 67 critically ill patients with severe sepsis or

septic shock randomized 1:1 to placebo versus 2 µg intravenous calcitriol supplementation. The primary outcome was plasma hCAP-18 protein levels assessed at 24 h. The investigators found that subjects randomized to calcitriol supplementation had increases in 24 h leukocyte mRNA expression of cathelicidin and the anti-inflammatory cytokine IL-10 but not plasma protein levels [211].

Trials in critically ill patients with ARDS suggest that oral high-dose cholecalciferol may improve length of stay and integrity of the alveolar–capillary barrier. The High-Dose Vitamin D in Lung Failure study was a randomized, double-blind, placebo-controlled, single-center trial of 31 ventilator-dependent ICU patients designed to evaluate the efficacy and safety of oral high-dose vitamin D<sub>3</sub> (placebo vs. 250,000 IU vs. 500,000 IU) [219]. Patients treated with vitamin D<sub>3</sub> demonstrated a statistically higher 25(OH)D and cathelicidin (LL-37) levels, shortened hospital length of stay, and nonsignificant decreases in ICU length of stay and duration of mechanical ventilation. Further, in the Vitamin D Open Label Replacement Esophagectomy study (UKCRN ID 11994), investigators show that 200,000 IU oral cholecalciferol supplementation prior to esophagectomy reduced the observed changes of in vivo measurements of alveolar capillary damage seen in vitamin D–deficient patients [220]. Perioperative changes were determined in an in vivo measure of the integrity of the alveolar–capillary barrier, namely extravascular lung water accumulation (extravascular lung water index [EVLWI]), and pulmonary vascular permeability index (PVPI) using a PiCCO<sub>2</sub> catheter. Severe vitamin D deficiency (25-(OH)D<sub>3</sub> <20 nmol/L) was associated with an increased accumulation of extravascular lung water and evidence of increases of PVPI, a marker of alveolar capillary permeability. Patients supplemented with vitamin D prior to esophagectomy had significantly reduced changes in EVLWI and PVPI than placebo-exposed patients.

The Vitamin D to Prevent Lung Injury Following Esophagectomy trial was a multicenter double-blind, randomized, placebo-controlled trial of high-dose vitamin D in 79 patients undergoing esophagectomy [221,222]. The primary outcome was extravascular lung water index at the end of esophagectomy. Despite effective increase in blood 25(OH)D concentrations and decreased changes in postoperative pulmonary vascular permeability index, the trial was neutral for the primary outcome.

RECTIFY was a single-center, randomized, double-blind, placebo-controlled trial of early high-dose enteral vitamin D<sub>3</sub> supplementation in emergently admitted neurocritical care patients with 25(OH)D ≤ 20 ng/mL [223]. 436 patients were to be randomized with the primary outcome being length of hospital stay. The trial

was halted at interim analysis with 274 patients enrolled for medical futility.

VIOLET was a multicenter, randomized, double-blind, placebo-controlled phase III trial of early high-dose enteral vitamin D<sub>3</sub> supplementation in vitamin D–deficient patients at high risk for ARDS and mortality [16]. Three thousand adult subjects with 25(OH)D ≤ 20 ng/mL were to be recruited from the emergency department with intention to admit to ICU, or ICU patients within 48 h of admission. To be enrolled, patients required acute risk factors for ARDS and mortality directly contributing to the need for ICU admission. Subjects were randomized to high-dose enteral vitamin D<sub>3</sub> or placebo. The VIOLET trial did not find a difference in 90-day all-cause mortality. Recruitment of patients in the emergency department resulted in a cohort with mild critical illness. Half of the VIOLET cohort had a SOFA score ≤ 5. The trial was designed to study patients at high risk for ARDS, but a small proportion of the trial subjects had ARDS or developed new ARDS in 7 days [224].

As noted in the VITdAL-ICU trial [15], critically ill patients likely to benefit from high-dose vitamin D are those with a baseline of 25(OH)D ≤ 12 ng/mL. Inclusion of patients with 25(OH)D >12–20 ng/mL biases the VIOLET trial result to the null as these patients may be less likely to benefit. Similar to the VITdAL-ICU trial, in 25% of VIOLET subjects who received high-dose vitamin D, the plasma 25(OH)D was less than 30 ng/mL at day 3, which also biases the trial result to the null [224]. Such lack of response may confound the intervention outcome relationship as there is a systematic difference between those in the intervention group with plasma 25(OH)D < 30 ng/mL versus those with plasma 25(OH)D ≥ 30 ng/mL. The ongoing VITDALIZE study is designed to evaluate the efficacy of high-dose enteral vitamin D<sub>3</sub> in severely vitamin D–deficient population with higher severity of critical illness [225]. The VITDALIZE study will randomize 2400 adult patients with 25(OH)D ≤ 12 ng/mL to high-dose enteral vitamin D<sub>3</sub> or placebo within 72 h after ICU admission.

Trials in critical illness are hampered by the heterogeneity of the population where the effect of treatment can be dampened, thus decreasing the study power [224,226]. In the VITdAL-ICU trial, for example, half of the patients who received high-dose oral vitamin D<sub>3</sub> did not have the expected increase of 25(OH)D in 72 h [15,141]. Such heterogeneity of treatment effect exists even with enriching trials by only enrolling patients with 25(OH)D levels below a specific serum 25(OH)D target [15]. Similar to administering antibiotics to suspected infections of unknown etiology, the identification of patients who may benefit from intervention is currently limited.

Adequate sample size is essential to determine if differences in outcomes between intervention groups are present [227]. Sample size in randomized trials is determined by the estimated outcome proportion in the placebo group relative to the estimated outcome proportion in those who receive the intervention. Table 106.1 shows the sample size ranges required to have the power to detect differences in the primary outcome (28-day mortality) and vitamin D<sub>3</sub> intervention. In trial design, the event rate of the placebo group must be estimated prior to randomization. There is a high likelihood that such a trial will be underpowered for the outcome of interest unless the sample size is quite large. Most existing vitamin D<sub>3</sub> interventional trials are underpowered for mortality [228].

With the use of research tools such as metabolomics, investigators are beginning to determine metabolic phenotypes or endotypes at ICU admission, which have potential to identify patient subgroups who may benefit from specific therapies such as vitamin D<sub>3</sub> intervention [141,229]. Metabolomics allows for a window into how interventions alter metabolism as a whole and differences in the intervention response among patient subgroups [142,230]. In the future, translation of research findings to point-of-care determination of such subgroups may allow practitioners to provide personalized therapeutics.

## 5.4 Vitamin D dose in critical illness

Recommended adequate intake for adults  $\leq$  age 70 is 600 IU/day and 800 IU/day for  $>$  age 70 [231]. These recommendations can result in a large portion of adults becoming vitamin D deficient. In general, sun avoidance behavior combined with a low proportion of time spent outdoors has decreased sun exposure. Too little vitamin D dietary supplementation in the setting of low sun exposure can result in low vitamin D levels [232]. Most critically ill patients have low vitamin D levels [4–11].

Comorbidities, severity of illness, and organ dysfunction likely contribute to the low 25(OH)D levels observed in ICU patients [6].

The dose of vitamin D supplementation in the critically ill required to achieve a normal 25(OH)D is much higher than current adequate intake. In the critically ill, malabsorption from gastrointestinal edema and inflammation limits the effectiveness of oral and enteral formulations. In general, the efficiency of vitamin D supplementation is dependent on gastrointestinal absorption, renal hydroxylation, hepatic chylomicron transport, and liver degradation of 25(OH)D. The response to vitamin D supplementation may be blunted in critical illness due to organ dysfunction (gastrointestinal, renal, hepatic). In addition, an increase in tissue vitamin D requirement in the critically ill results in heightened tissue level conversion of 25(OH)D to active 1,25(OH)<sub>2</sub>D [233]. Healthy adults have a two- to threefold increased response in 25(OH)D levels when supplemented with single high-dose oral cholecalciferol (300,000–600,000 units) compared with the critically ill [234].

From supplementation studies in the critically ill, we know that at least 120,000 IU total oral cholecalciferol delivered over the course of 1 week is needed to increase 25(OH)D in critically ill septic patients [201]. In the VITdAL-ICU and VIOLET trials, one dose of oral 540,000 IU cholecalciferol was effective in increasing the 25(OH)D levels  $>$  20 ng/mL in most patients within 2 days' time [15,16,200]. In the VITdAL-ICU trial and the pilot trial, large, unpredictable interindividual differences in serum 25(OH)D response to the of oral 540,000 IU cholecalciferol were observed [15,200]. Further, in the VITdAL-ICU and VIOLET trials, only half of patients treated with 540,000 IU vitamin D<sub>3</sub> reached serum 25(OH)D levels of 30 ng/mL or higher [15,16]. This response to vitamin D<sub>3</sub> may be evidence of altered gastrointestinal function of critical illness and/or to renal and drug-related alteration of the hepatic CYP2R1 [235].

**TABLE 106.1** Sample size to detect 10%–50% reduction in 28-day mortality with 90% power assuming statistical significance level at 0.05

		Relative percent reduction in 28-day mortality rate in vitamin D <sub>3</sub> intervention group					
28-day mortality rate in placebo group	50%	40%	30%	25%	20%	15%	10%
40.00%	238	378	684	992	1560	2784	6286
35.00%	284	458	832	1208	1904	3412	7726
30.00%	348	560	1026	1496	2364	4246	9646
25.00%	438	708	1300	1900	3008	4748	12334
20.00%	572	928	1710	2504	3974	7170	16368
15.00%	796	1296	2394	3510	5582	10094	23088

200 IU cholecalciferol packaged in a multivitamin preparation is common in standard parenteral and enteral formulations. This dose is far from what is required to normalize vitamin D status rapidly. Rapid normalization of 25(OH)D may be needed to fully benefit from vitamin D sufficiency during critical illness [236]. Though studies on intravenous vitamin D<sub>3</sub> formulation are published in the human and veterinary literature, it is not available commercially. Intravenous vitamin D<sub>3</sub> would be ideal for high-dose supplementation and bypass the gastrointestinal malabsorption and the hepatic first-pass effect common in the ICU population [237]. Further, although there are few studies to support the use of supplemental calcifediol [25(OH)D] or calcitriol [1,25(OH)<sub>2</sub>D] in the ICU, it may be a reasonable approach to quickly increase vitamin D in critically ill patients without efficient liver or kidney hydroxylation of cholecalciferol [211] (see Chapter 73 for more detailed discussion of calcifediol).

### 5.5 Is vitamin D supplementation safe?

The safe tolerable upper intake level (UL) for adults is 10,000 IU/d per the Endocrine Practice Guidelines Committee [21], while the Institute of Medicine has a more conservative approach with an UL of 4000 IU/d [20]. The Office of Dietary Supplements (ODS) recommends a toxicity threshold of serum 25(OH)D levels of 200–240 ng/mL and administration level of 10,000–40,000 IU per day [238]. These recommendations are not made in the context of critical illness, and it is not clear what the ideal dose for vitamin D supplementation should be in the critically ill. As demonstrated in trials, high-dose supplementation is needed to increase 25(OH)D levels in the critically ill. High doses of vitamin D supplementation can lead to vitamin D intoxication, which has the rare potential to be life-threatening.

Vitamin D intoxication is not likely at intakes below 10,000 IU per day, but any elevated dose over time may cause untoward health effects [238]. Toxicity cases are usually related to accidental and protracted consumption of over 40,000 IU per day [239]. Vitamin D toxicity has been described in patients with *CYP24A1* mutations causing failure to metabolize 1,25(OH)<sub>2</sub>D [240]. Important issues with trial design and the potential adoption of high-dose vitamin D in the ICU are the safety profile of high or “supraphysiologic” (relative to current adequate intake) doses of vitamin D and the risk of toxicity. The IU dose of vitamin D needed for toxicity in humans is not known. The lethal dose in 50% (LD50) in rats is 352 mg/kg oral vitamin D<sub>3</sub>, which is equal to 14 million IU/kg, 28 times the dose given in the VITdAL-ICU trial [241]. In general, vitamin D toxicity in the form of hypercalcemia is only seen

when serum 25(OH)D is kept above 150–200 ng/mL [242]. In randomized controlled trials that utilized ≥100,000 IU single-dose oral vitamin D<sub>3</sub>, the adverse events demonstrated have been rare mild hypercalcemia [15,200,201] and the increase in falls/fractures in older community-dwelling women [212].

Studies have shown the safety profile and efficacy in increasing 25(OH)D of single high-dose cholecalciferol administration in rheumatologic and elderly patients [243,244] and in the ICU [15,200]. In an outpatient elderly population of 63 subjects who received an oral 500,000 IU vitamin D<sub>3</sub> loading dose, the mean increase in 25(OH)D was 23 ng/mL without hypercalcemia [243]. Similarly, in a study of rheumatology outpatient population of 33 subjects who received a single loading dose of oral 300,000 IU vitamin D<sub>3</sub>, the mean increase in 25(OH)D was 27 ng/mL after 3 months with two cases of mild hypercalcemia reported [244]. Further, in the pilot study of the VITdAL-ICU trial of 25 medical ICU patients, a single dose of oral 540,000 IU vitamin D<sub>3</sub> normalized 25(OH)D in most patients and showed no hypercalcemia [200]. In the VITdAL-ICU trial of 475 ICU patients, a single dose of oral 540,000 IU vitamin D<sub>3</sub> followed by monthly oral 90,000 IU vitamin D<sub>3</sub> showed no adverse effects other than mild hypercalcemia in a small number of subjects [15]. The 2 highest subject 25(OH)D levels achieved in the VITdAL-ICU trial were much lower than what is considered toxic 25(OH)D [15]. In other high-dose oral vitamin D<sub>3</sub> intervention studies in the ICU [200,201], the peak 25(OH)D level achieved was 64 ng/mL, well below toxic 25(OH)D levels. The small numbers of subjects with adverse effect (mild reversible hypercalcemia) in the high-dose oral vitamin D<sub>3</sub> trials are reassuring but only in the context of the small sample size.

As it appears that high oral doses of vitamin D<sub>3</sub> are required to improve 25(OH)D status in the critically ill, it is important to review the potential for unexpected harm with such a dosing strategy. Specific populations may be very sensitive to vitamin D<sub>3</sub> administration and include those with sarcoidosis and *Mycobacterium* infections, myeloma patients treated with thiazide diuretics, and those with mutations in *CYP24A1* [245]. If efficacy of high-dose vitamin D<sub>3</sub> is established in randomized controlled trials on specific populations and subsequently adopted by the ICU community on a wide scale, surveillance of drug adverse effects will be required to identify populations at risk for adverse events.

Though response to high-dose oral vitamin D<sub>3</sub> in the critically ill is not expected to be similar to outpatient subjects, it is important to consider adverse findings in trials of high-dose vitamin D<sub>3</sub>. In a landmark trial of 2256 community-dwelling women randomized to oral 500,000 IU cholecalciferol or placebo, an increased risk

of falls and fractures was demonstrated in the vitamin D group. The incidence rate for falls was increased by 15% and for fractures by 26% in the vitamin D group [212]. In a small subset with serum available ( $n = 131$ ), the median baseline serum 25(OH)D was 20 ng/mL. Evaluation of bone turnover markers in a study of 12 elderly outpatients administered oral 600,000 IU cholecalciferol compared with 24 control patients. Investigators noted increased C-terminal-telopeptides of type I collagen and cross-linked N-telopeptide of type I collagen (bone resorption markers) within 24 h of supplementation which resolved by 90 days [246]. In the context of the relatively short half-life of cholecalciferol (2–3 weeks) and the increased risk of falls and fractures, a high-dose vitamin D supplementation given once per year may be harmful in this population. The reason for the increase in falls and fracture is not known, but high oral vitamin D<sub>3</sub> may upregulate 25-hydroxyvitamin D-24-hydroxylase, which in turn degrades active vitamin D, thus decreasing tissue availability [247]. If this potential defensive catabolism occurs in the face of high-oral vitamin D<sub>3</sub>, perhaps giving smaller doses with higher frequency (4000 to 10,000 IU) [20,21] could be more efficacious in the ICU.

## 6. Conclusions

Vitamin D in the ICU setting is understudied. It is not known what the acute effects of treatment of vitamin D deficiency in the ICU setting, where multiple drugs (and potential drug interactions) and multiple interventions are going on at the same time, will be. 25(OH)D testing is not routine in the ICU, nor is it recommended in the general population, unless there are clear indications for suspecting vitamin D deficiency [20]. Neither the IOM nor the Endocrine Society addresses the issue of vitamin D deficiency in the ICU setting [21].

Vitamin D supplementation is not recommended routinely for mortality benefits in any situation, given current knowledge. Some recommendations or guidelines for the screening and treatment of vitamin D deficiency in the ICU setting do exist [248]. There are no standard clinical protocols for vitamin D supplementation in the ICU setting. Over the next several years, further interventional trials sufficiently powered to detect differences in outcomes may shed light on the efficacy of vitamin D supplementation in the ICU and specific populations that may benefit. Therefore, treating ICU patients with vitamin D to alter ICU outcomes at any dose at this time remains experimental and not standard of care [16].

## 7. Summary points

- Low vitamin D levels are commonly found in critically ill patients.
- Vitamin D has important roles in the genetic, epigenetic, and metabolomic response to critical illness.
- Benefit of vitamin D supplementation in the critically ill is not consistently shown.

- #
- 1,24,25-trihydroxyvitamin D, 1076
- 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D), 11, 78, 126, 149, 185–186, 223, 248, 265, 304, 352, 412, 589, 594, 603–604, 607–608, 664–665, 720–721, 996–999, 1001–1002, 1011–1012, 1059, 1092, 1185–1186
- and antimicrobial peptides in antiviral immunity, 1017–1018
- and antiviral CD4 T cell immunity, 1019–1021
- and antiviral CD8 T cell immunity, 1021 and antiviral cytokine and chemokine responses, 1018–1019
- and B cell responses to viruses, 1021–1022
- catabolism in chronic kidney disease, 592–594
- corrects impaired 25(OH)D availability to nonrenal 1 $\alpha$ -hydroxylase in CKD, 596–599
- decreased clearance of, 634
- deficiency, 599–600
- role in pathogenesis of secondary hyperparathyroidism in chronic kidney disease, 599f
- 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D)-VDR-activatable enhancer elements, 457
- endogenous production of, 630–634
- evolutionary aspects of 1,25(OH)<sub>2</sub>D induction of AMPs and PRRs, 1000–1001
- feedback, 593
- hereditary resistance to, 314
- induces antimicrobial peptides implicated in antibacterial immunity, 997–998
- induction
- of ACE2 gene expression, 607
- of FGF23 synthesis, 600
- and innate immune sensing of viruses, 1016–1017
- mechanism of 1,25(OH)<sub>2</sub>D action relevant to HVDNR, 364–365
- and natural killer cell responses, 1019
- and nonclassical immune cells, 1002
- 1,25-(OH)<sub>2</sub>D-mediated hypercalcemia, 465–466
- 1,25(OH)<sub>2</sub>D-mediated suppression, 607 of ADAM17 gene, 598
- 1,25(OH)<sub>2</sub>D/VDR, 601
- 1,25(OH)<sub>2</sub>D/VDR suppression of ADAM17 gene, 601
- alterations in 1,25(OH)<sub>2</sub>D/VDR endocrine, 596–599
- complex, 598, 602
- pathogenesis of parathyroid hyperplasia and 1,25(OH)<sub>2</sub>D resistance in CKD, 600f
- production by extrarenal 1 $\alpha$ -Hydroxylases in chronic kidney disease, alterations in, 594–596
- promotes expression of pattern recognition receptors and cytokines, 999–1000
- regulates release of reactive oxygen species, 1000
- regulation of antibacterial innate immunity, in vivo evidence for, 1002–1004
- regulation of gene expression by, 364–365
- replacement therapy, 587
- toxicity, 628–629
- 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>), 457, 625, 628–629, 631, 634–637, 652, 679, 682–683, 687–688, 693–696, 702f, 741, 772–774, 798, 904, 918, 968, 1109, 1130, 1153–1155
- and acquired immunity, 766–768
- and analogs and impact of genomic ancestry, chemotherapy of PCA with, 926–927
- clinical use, 1214–1217
- combination of vitamin D analogs with other therapies, 1216–1217
- nail psoriasis treatment, 1216
- psoriatic lesions treatment in HIV patients, 1216
- scalp psoriasis treatment, 1216
- skin lesions treatment in children, 1216
- treatment of face and flexures, 1216
- downregulation of c-MYC expression in 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced differentiation, 762–763
- effects, 800f–802f, 804f
- genes in human colon carcinoma cells, 872f
- and hematopoiesis, 766
- hyperresponsivity in human osteoclast precursors, overexpression of
- TAF12 is sufficient to induce, 654–655
- and innate immunity, 766
- interact ions, 803f
- interplay between 1,25(OH)<sub>2</sub>D<sub>3</sub> and CD4<sup>+</sup>Tr1 cells in MS, 1149
- 1,25(OH)<sub>2</sub>D<sub>3</sub>-induced hypercalcemia, 633
- marrow stromal cells derived from P62<sup>P394L</sup> knock-in mice and P62<sup>P392L</sup> Paget's patients hyperresponsive to 1,25(OH)<sub>2</sub>D<sub>3</sub> and display enhanced RANKL production in response to, 657
- mechanism of action of 1,25(OH)<sub>2</sub>D<sub>3</sub> on osteoclast formation, 652
- mechanism of action of 1,25(OH)<sub>2</sub>D<sub>3</sub> in colorectal cancer, 868–881, 868
- antagonism of Wnt/ $\beta$ -catenin pathway, 868–871
- antiangiogenic, antiinflammatory, immunomodulatory, and detoxifying effects, 874–878
- effects in colon cancer-associated fibroblasts, 878–880
- effects of 1,25(OH)<sub>2</sub>D<sub>3</sub> in colorectal stem cells–derived organoids, 880–881
- effects on colon cancer cell proliferation, survival, and differentiation, 871–874
- target genes in colon cancer cells, 871–872
- mechanisms of resistance toward anticancer actions of, 922–923
- 1,25(OH)<sub>2</sub>D<sub>3</sub>-mediated gene expression, 843
- modulation of IL-10 and CD4<sup>+</sup>Tr1 cell production, 1147–1148
- multilevel antagonism of Wnt/ $\beta$ -catenin signaling pathway, 862f
- osteoclast precursors from TRACP–TAF12 transgenic mice hyperresponsive to, 655
- as potential CD4<sup>+</sup>Tr1 cell inducer in MS patients, 1148–1149
- protects against CRC acting on carcinoma cells, cancer-associated fibroblasts, and cancer stem cells, 879f
- regulated genes, 841–842
- regulation of breast cancer stem cell populations, 847–848

- 1,25-dihydroxyvitamin D<sub>3</sub> (1,25(OH)<sub>2</sub>D<sub>3</sub>)

# Vitamin D

## Volume Two: Disease and Therapeutics

### Editor-in-Chief:

Martin Hewison, PhD, University of Birmingham, Birmingham, UK

### Associate Editors:

Roger Bouillon, MD, PhD, FRCP (London), Catholic University of Leuven (K.U. Leuven), Leuven, Belgium

Edward Giovannucci, MD, ScD, Harvard TH Chan School of Public Health, Boston, MA, USA

David Goltzman, MD, McGill University, and Endocrine Division, McGill University Health Centre, Montreal, QC, Canada

Mark B Meyer, PhD, University of Wisconsin-Madison, Madison, WI, USA

JoEllen Welsh, PhD, University at Albany Cancer Research Center, Rensselaer, NY, USA

### Key Features

- A comprehensive reference ranging from basic biochemistry, cell biology, and physiology principles to the clinical diagnostic and management implications of vitamin D
- Saves researchers and clinicians time in quickly accessing the very latest details on the diverse scientific and clinical aspects of vitamin D, as opposed to searching through thousands of journal articles
- Chapters written by the most prominent and well-published names in the field

Vitamin D deficiency is a worldwide problem linked to numerous diseases affecting men, women, and children of all ages. Enormous progress in the study of vitamin D has been made since the first edition of this highly acclaimed book was published nearly 25 years ago, and current research continues to draw headlines. Vitamin D, Fifth Edition, continues to build on the successful formula from previous editions, taking the reader from the basic elements of fundamental research to the most sophisticated concepts in therapeutics. The two comprehensive volumes provide investigators, clinicians, and students with a comprehensive, definitive, and up-to-date compendium of the diverse scientific and clinical aspects of vitamin D, where each area is covered by both basic and clinical experts in the field.

**In Volume I: Biochemistry, Physiology and Diagnostics**, international experts in endocrinology, bone biology, and human physiology take readers through the basic research of vitamin D. This impressive reference presents a comprehensive review of the multifaceted actions of vitamin D relating both to skeletal and extraskeletal action. Researchers from all areas of vitamin D will gain insight into how clinical observations and practices can feed back into the research cycle and will, therefore, be able to develop more targeted genomic and proteomic and metabolomic insights into the mechanisms of disease.

**Volume II: Health, Disease and Therapy** authoritatively covers the evidence for new roles of vitamin D, ranging from organ transplantation to cancer, diabetes, inflammatory bowel disease, multiple sclerosis, and renal disease. The coverage is appropriately broad, drawing on aspects of internal medicine, pediatrics, nutrition, orthopedics, oncology, neurology, obstetrics and gynecology, and immunology, as well as new areas for vitamin D including liver metabolism, veterinary medicine, and ICU care—including COVID-19. Clinical researchers will gain a strong understanding of the molecular basis for a particular disease and better understand future directions for research in this still-growing field.
